Note: Properties are estimated or based on incomplete data.

Tables 17 through 19 contain physical property information on a mixture of various molecular weight dimethylsiloxane polymers (Dow Corning 1989) and d-limonene. *Note*: the information on d-limonene is limited; it is based on measurements made over small data temperature ranges or simply on standard physical property estimation techniques. The compound is an optically active terpene (molecular formula $C_{10}H_{16}$) derived as an extract from orange and lemon oils. The "d" indicates that the material is dextrorotatory, which is a physical property of the material, but does not affect the transport properties of the material significantly.

The mixture of dimethylsiloxane polymers can be used with most standard construction materials; d-limonene, however, can be quite corrosive, as it easily autooxidizes at ambient temperatures. This fact should be understood and considered before using d-limonene in a system.

CHAPTER 19

SORBENTS AND DESICCANTS

Desiccant Applications 19.1
Desiccant Cycle 19.1
Types of Desiccants 19.3
Desiccant Isotherms 19.5
Desiccant Life 19.5
Cosorption of Water Vapor and Indoor Contaminants 19.6

VIRTUALLY all materials are desiccants; that is, they attract and hold water vapor. Wood, natural fibers, clays, and many synthetic materials attract and release moisture like commercial desiccants do, but they lack the holding capacity of what are known as desiccant materials. For example, woolen carpet fibers attract up to 23% of their dry weight in water vapor, and nylon can take up almost 6% of its weight in water. In contrast, a commercial desiccant takes up between 10 and 1100% of its dry weight in water vapor, depending on its type and the moisture available in the environment. Furthermore, commercial desiccants continue to attract moisture even when the surrounding air is quite dry, a characteristic that other materials do not share.

All desiccants behave in a similar way—they attract moisture until they reach equilibrium with the surrounding air. Moisture is usually removed from the desiccant by heating it to temperatures between 120 and 500 °F and exposing it to a scavenger airstream. After the desiccant dries, it must be cooled so that it can attract moisture once again. Sorption always generates sensible heat equal to the latent heat of the water vapor taken up by the desiccant, plus an additional heat of sorption that varies between 5 and 25% of the latent heat of the water vapor. This heat is transferred to the desiccant and to the surrounding air.

The process of attracting and holding moisture is described as either adsorption or absorption, depending on whether the desiccant undergoes a chemical change as it takes on moisture. *Adsorption* does not change the desiccant, except by the addition of the weight of water vapor, similar in some ways to a sponge soaking up water. *Absorption*, on the other hand, changes the desiccant. An example of this is table salt, which changes from a solid to a liquid as it absorbs moisture.

Sorption refers to the binding of one substance to another. Sorbents are materials that have an ability to attract and hold other gases or liquids. They can be used to attract gases or liquids other than water vapor, a characteristic that makes them very useful in chemical separation processes. *Desiccants* are a subset of sorbents; they have a particular affinity for water.

DESICCANT APPLICATIONS

Desiccants can dry either liquids or gases, including ambient air, and are used in many air-conditioning applications, particularly when:

- The latent load is large in comparison to the sensible load.
- The cost of energy to regenerate the desiccant is low when compared with the cost of energy to dehumidify the air by chilling it below its dew point.
- The moisture control level required in the space would require chilling the air to subfreezing dew points if compression refrigeration alone were used to dehumidify the air.
- The temperature control level required by the space or process requires continuous delivery of air at subfreezing temperatures.

In any of these situations, the cost of running a vapor compression cooling system can be very high. A desiccant process may offer considerable advantages in energy, the initial cost of equipment, and maintenance.

Since desiccants are able to absorb more than simply water vapor, they can remove contaminants from airstreams to improve indoor air quality. Desiccants have been used to remove organic vapors, and in special circumstances, to control microbiological contaminants (Batelle 1971).

Desiccants are also used in drying compressed air to low dew points. In this application, moisture can be removed from the desiccant without heat. Desorption is accomplished using differences in vapor pressures compared to the total pressures of the compressed and ambient pressure airstreams.

Hines *et al.* (1991) have also confirmed the usefulness of desiccants in removing vapors that can degrade indoor air quality. Desiccant materials are capable of adsorbing hydrocarbon vapors at the same time they are collecting moisture from air. These desiccant cosorption phenomena show promise of improving indoor air quality in typical building HVAC systems.

Finally, desiccants are used to dry the refrigerant circulating in air-conditioning and refrigeration systems. This reduces corrosion in refrigerant piping and prevents valves and capillaries from becoming clogged with ice crystals. In this application, the desiccant is not regenerated; it is discarded when it has adsorbed its limit of water vapor.

This chapter discusses the water sorption characteristics of desiccant materials and explains some of the implications of those characteristics in ambient pressure air-conditioning applications. Information on other aspects of desiccants can be found in Chapters 7, 27, 32, and 34 of the 1990 ASHRAE *Handbook—Refrigeration*, and Chapters 12, 14 through 24, 28, and 40 of the 1992 ASHRAE *Handbook—Systems and Equipment*.

DESICCANT CYCLE

Practically speaking, all desiccants function by the same mechanism—transferring moisture because of a difference between the water vapor pressure at their surface and that of the surrounding air. When the vapor pressure at the desiccant surface is lower than that of the air, the desiccant attracts moisture. When the surface vapor pressure is higher than that of the surrounding air, the desiccant releases moisture.

The preparation of this chapter is assigned to TC 3.5, Sorption.

Figure 1 shows the relationship between the moisture content of the desiccant and its surface vapor pressure. As the moisture content of the desiccant rises, so does the water vapor pressure at its surface. At some point, the vapor pressure at the desiccant is the same as that of the air—the two are in equilibrium. Then moisture cannot move in either direction until some external force changes the vapor pressure at the desiccant or in the air.

Figure 2 shows the effect of temperature on the vapor pressure at the desiccant. Both higher temperatures and increased moisture content increase the vapor pressure at the surface. When the surface vapor pressure exceeds that of the surrounding air, moisture leaves the desiccant—a process called reactivation or regeneration. After the desiccant is dried (reactivated) by the heat, its vapor pressure remains high, so that it has very little ability to absorb moisture. Cooling the desiccant reduces its surface vapor pressure so that it can absorb moisture once again. The complete cycle is illustrated in Figure 3.

The economics of desiccant operation depends on the energy cost of moving a given material through this cycle. The dehumidification of air (loading the desiccant with water vapor) generally proceeds without energy input, other than fan and pump costs.

The major portion of energy is invested in regenerating the desiccant (moving from point 2 to point 3) and cooling the desiccant (point 3 to point 1). Regeneration energy is equal to the sum of three variables:

- The heat necessary to raise the desiccant to a temperature high enough to make its surface vapor pressure higher than the surrounding air
- The heat necessary to vaporize the moisture it contains (about 1060 Btu/lb)
- The small amount of heat from desorption of the water from the desiccant

The cooling energy is proportional to the mass of the desiccant, and the difference between its temperature after regeneration and the lower temperature that allows the desiccant to remove water from the airstream once again.

The cycle is similar when desiccants are regenerated using pressure differences in a compressed air application. The desiccant is saturated in a high-pressure chamber, *i.e.*, that of the compressed air. Then valves open, isolating the compressed air from the material, and the desiccant is exposed to air at ambient pressure. The vapor pressure of the saturated desiccant is much higher than ambient air at normal pressures; thus the moisture leaves the desiccant for the surrounding air. An alternate desorption stategy uses a small portion of the dried air, returning it to the moist desiccant bed to reabsorb the moisture, then venting the air to the atmosphere at ambient pressures.

To quantify the range of vapor pressures in which the desiccant must operate in space-conditioning applications, see Table 1. It converts the relative humidity at 70 °F to dew point and, therefore, moisture content and the corresponding vapor pressure. The greater the difference between the air and desiccant surface vapor

pressures, the greater the ability of the material to absorb moisture from the air at that moisture content.

The ideal desiccant for a particular application depends on the range of water vapor pressures that are likely to occur in the air, the temperature level of the regeneration heat source, and the moisture sorption and desorption characteristics of the desiccant within those constraints. In commercial practice, however, most desiccants can be made to perform well in a wide variety of operating situations through careful engineering of the mechanical aspects of the dehumidification system. Some of these hardware issues are discussed in Chapter 22 of the 1992 ASHRAE *Handbook—Systems and Equipment.*

TYPES OF DESICCANTS

Desiccants can be solids or liquids and can hold moisture through adsorption or absorption as described earlier. Most absorbents are liquids, and most adsorbents are solids.

Liquid Absorbents

Liquid absorption dehumidification can best be illustrated by comparing it to the operation of an air washer. When air passes through an air washer, its dew point approaches that of the temperature of the water supplied to the machine. More humid air is dehumidified and less humid air is humidified. In a similar manner, a liquid absorption dehumidifier contacts air with a liquid desiccant solution. The liquid has a vapor pressure lower than water at the same temperature, and the air passing over the solution approaches this reduced vapor pressure; it is dehumidified.

The vapor pressure of a liquid absorbtion solution is directly proportional to its temperature and inversely proportional to its concentration. Figure 4 illustrates the effect of increasing desiccant concentration on the water vapor pressure at its surface. The figure shows the vapor pressure of various solutions of water and triethylene glycol, a common commercial desiccant. As the glycol content of the mixture increases, its vapor pressure decreases. This pressure difference allows the glycol solution to absorb moisture from the air whenever the vapor pressure of the air is greater than that of the solution.

From a slightly different perspective, the vapor pressure of a given concentration of absorbent solution approximates the vapor pressure values of a fixed relative humidity line on a psychrometric chart. Higher solution concentrations result in lower equilibrium relative humidities, allowing the absorbent to dry air to lower levels.

Figure 5 illustrates the effect of temperature on the vapor pressure of lithium chloride (LiCl), another liquid desiccant in common use. A solution that is 25% lithium chloride has a vapor pressure of 0.37 in. Hg at a temperature of 70 °F. If the same 25% solution is heated to 100 °F, its vapor pressure more than doubles to 0.99 in. Hg. This can be expressed another way as the 70 °F, 25% solution is in equilibrium with air at a 51 °F dew point. The same 25% solution at 100 °F is at equilibrium with an airstream at a 79 °F dew point. The warmer the desiccant, the less moisture it can attract from the air.

In standard practice, the behavior of a liquid desiccant can be controlled by adjusting its concentration, its temperature, or both. Desiccant temperature is controlled by simple heaters and coolers. Concentration is controlled by heating the desiccant to drive moisture out into a waste airstream or directly to the ambient.

Commercially available liquid desiccants have an especially high water-holding capacity. Each molecule of lithium chloride, for example, can hold two water molecules, even in the dry state. Above two water molecules per molecule of LiCl, the desiccant becomes a liquid and continues to absorb water. If the solution is in equilibrium with air at a 90% rh air moisture condition,

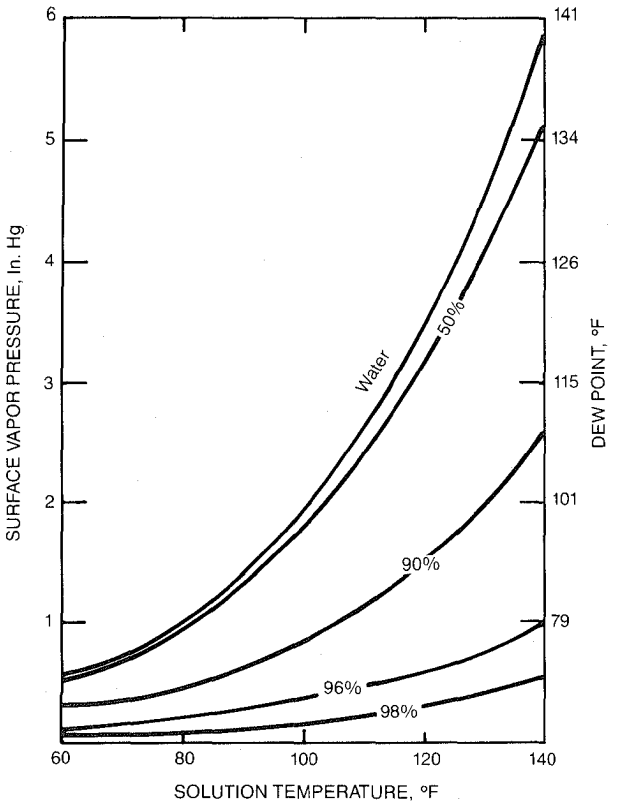

Fig. 4 Surface Vapor Pressure of Water-Triethylene Glycol Solutions
(from *A Guide to Glycols* 1981)

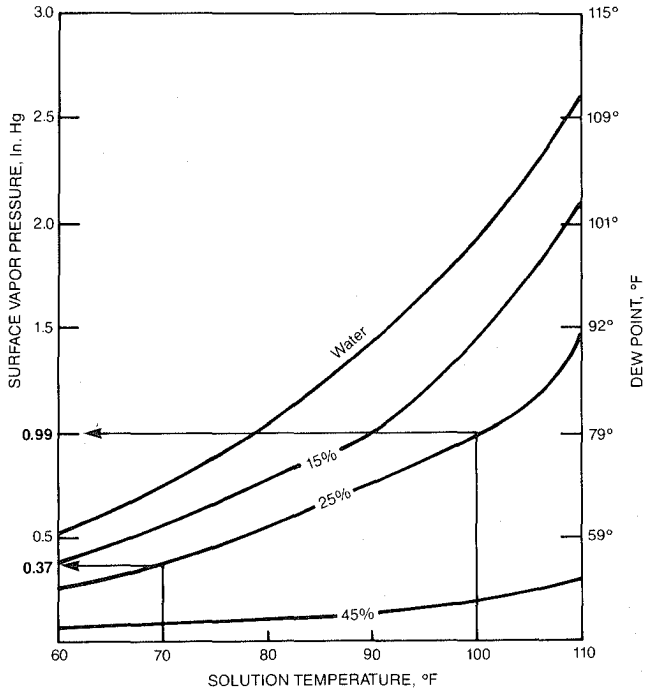

Fig. 5 Surface Vapor Pressure of Water-Lithium Chloride Solutions
(from *Lithium Chloride Technical Data* 1988)

approximately 26 water molecules are attached to each molecule of LiCl. This represents a water absorption of more than 1000% on a dry mass basis.

As a practical matter, however, the absorption process is limited by the surface area of a desiccant exposed to the air being dehumidified and the contact time allowed for the reaction. More surface area and more contact time allows the desiccant to approach its theoretical capacity. Commercial desiccant systems reflect these realities either by spraying the desiccant onto an extended surface much like in a cooling tower, or holding a solution in a rotating extended surface with a large solution capacity.

Solid Adsorbents

Adsorbents are solid materials with a tremendous internal surface area per unit of mass; a single gram can have more than 50,000 ft^2 of surface area. Structurally, adsorbents resemble a rigid sponge, and the surface of the sponge in turn resembles the ocean coastline of a fjord. This analogy indicates the scale of the different surfaces in an adsorbent. The fjords can be compared to the capillaries in the adsorbent. The spaces between the grains of sand on the fjord beaches can be compared to the spaces between the individual molecules of the adsorbent, all of which have the capacity to hold water molecules. The bulk of the adsorbed water is contained by condensation into the capillaries, and the majority of the surface area that attracts individual water molecules is in the crystalline structure of the material itself.

Adsorbents attract moisture because of the electrical field at the desiccant surface. The field is not uniform in either force or charge, so it attracts water molecules that have a net opposite charge from specific sites on the desiccant surface. When the complete surface is covered, the adsorbent can hold still more moisture, as vapor condenses into the first water layer and fills the capillaries throughout the material.

As with liquid absorbents, the ability of an adsorbent to attract moisture depends on how much water is on its surface compared to how much water is in the air. That difference is reflected in the vapor pressure at the surface and in the air.

The capacity of solid adsorbents is generally less than the capacity of liquids. For example, a typical molecular sieve adsorbent will hold 17% of its dry mass in water when the air is at 70°F and 20% rh. In contrast, lithium chloride can hold 130% of its mass at the same temperature and relative humidity. But solid adsorbents have several other favorable characteristics.

For example, molecular sieves continue to adsorb moisture even when they are quite hot, allowing dehumidification of very warm airstreams. Also, several solid adsorbents can be manufactured to precise tolerances, with pore diameters that can be closely controlled. This means they can be tailored to adsorb a molecule of a specific diameter. Water, for example, has an effective molecular diameter of 3.2 nm. A molecular sieve adsorbent with an average pore diameter of 4.0 nm adsorbs water but has almost no capacity for larger molecules, such as organic solvents. This selective adsorption characteristic is useful in many applications. For example, several desiccants with different pore sizes can be combined in series to remove first water and then other specific contaminants from an airstream.

The adsorption behavior of solid adsorbents depends on (1) their total surface area, (2) the total volume of their capillaries, and (3) the range of their capillary diameters. A large surface area gives the adsorbent a larger capacity at low relative humidities. Large capillaries provide a high capacity for condensed water, which gives the adsorbent a higher capacity at high relative humidities. A narrow range of capillary diameters makes an adsorbent more selective in the vapor molecules it can hold; thus, some will fit and others will be too large to pass through the passages in the material.

In designing a desiccant, some trade-offs are necessary. For example, materials with large capillaries necessarily have a smaller surface area per unit of volume than those with smaller capillaries. As a result, adsorbents are sometimes combined to provide a high adsorption capacity across a wide range of operating conditions. Figure 6 illustrates this point. These are all silica gel adsorbents prepared for use in laboratory research. Each has a different internal structure, but since they are all silicas, they have similar surface adsorption characteristics. Gel 1 has large capillaries, making their total volume large, but the total surface area is small. It has a large adsorption capacity at high relative humidities, but adsorbs a small amount at low relative humidities.

In contrast, Gel 8 has a capillary volume one-seventh the size of Gel 1, but a total surface area almost twice as large. This gives it a higher capacity at low relative humidities, but a lower capacity to hold the condensed moisture that occurs at high relative humidities.

The table in Figure 6 illustrates the wide range of performance characteristics possible within a single class of adsorbent. The table shows three noncommercial silica gels. Silica gels and most other adsorbents can be manufactured to provide optimum performance in a specific application, balancing capacity against strength, mass, and other favorable characteristics (MVB Series Engineering Data 1986).

General classes of solid adsorbents include:

- Silica gels
- Zeolites
- Synthetic zeolites (molecular sieves)

(from Oscic *et al.* 1982)

- Activated aluminas
- Carbons
- Synthetic polymers

Silica gels are solid structures formed by condensing soluble silicates from solutions of water or other solvents. They have the advantages of a relatively low cost and relative simplicity of structural customizing. They are available as large spherical beads about 3/16 in. in diameter or as small as grains of a fine powder.

Zeolites are aluminosilicate minerals. They occur in nature and are mined rather than synthesized. Zeolites have a very open crystalline lattice which allows molecules like water vapor to be held inside the crystal itself like an object in a cage. Particular atoms of an aluminosilicate determine the size of the openings between the "bars of the cage," which in turn governs the maximum size of the molecule that can be adsorbed into the structure.

Synthetic zeolites, also called *molecular sieves*, are crystalline aluminosilicates manufactured in a thermal process. Controlling the temperature of the process and composition of the ingredient materials allows close control of the structure and surface characteristics of the adsorbent. At a somewhat higher cost, this provides a much more uniform product than naturally occurring zeolites.

Activated aluminas are oxides and hydrides of aluminum that are also manufactured in thermal processes. Their structural characteristics can be controlled by the gases and the temperature and duration of the thermal process.

Carbons are most frequently used for adsorption of gases other than water vapor, because they often have a greater affinity for the nonpolar molecules typical of organic solvents. Like other adsorbents, carbons have a large internal surface and especially large capillaries. This capillary volume gives them a high capacity to adsorb water vapor at relative humidities from 45 to 100%.

Solid polymers have potential for use as desiccants as well. Long molecules, like those found in polystyrenesulfonic acid sodium salt (PSSASS), are twisted together like the strands of string. The many sodium ions in the long PSSASS molecules each have the potential to bind several water molecules, and the spaces between the packed strings can also contain condensed water, giving the polymer a capacity exceeding that of many other solid adsorbents.

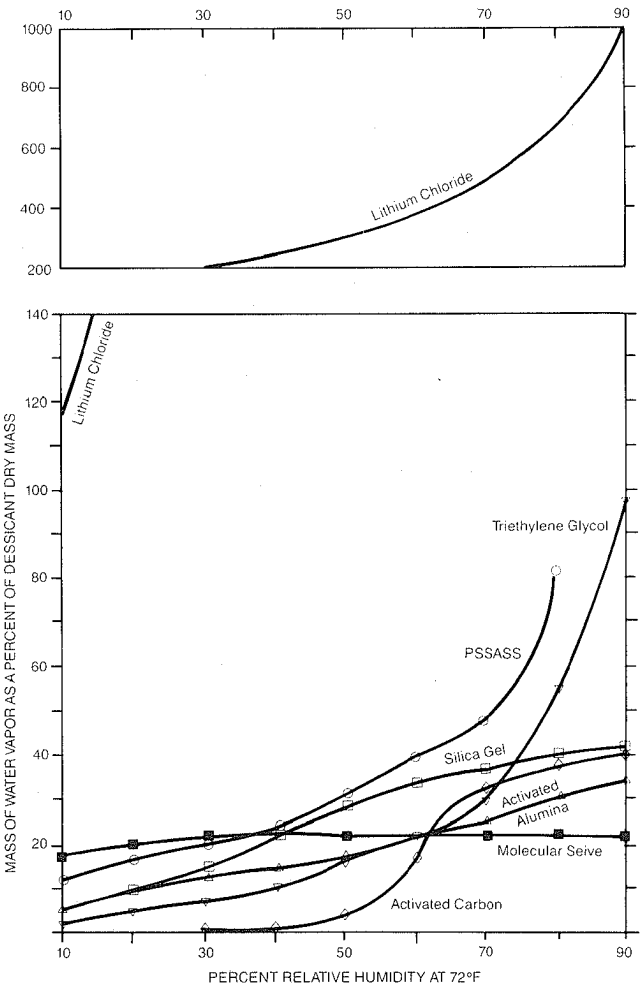
DESICCANT ISOTHERMS

Figure 7 shows a rough comparison of the sorption characteristics of different desiccants. Large variations from these isotherms occur because manufacturers use different methods to optimize the materials for different applications. The suitability of a given desiccant to a particular application is generally governed by the engineering of the mechanical system that presents the material to the airstreams as much as by the characteristics of the material itself.

Brunauer (1945) and Collier (1986, 1988) give details of desiccant equipment design and information about desiccant isotherm characteristics. Brunauer considers five basic isotherm shape types. Each isotherm shape is determined by the dominant sorption mechanisms of the desiccant, giving rise to its specific capacity characteristics at different vapor pressures. Isotherm shape can be important in designing the optimum desiccant for applications where a narrow range of operating conditions can be expected. Collier illustrates how an optimum isotherm shape can be used to ensure a maximum coefficient of performance in one particular air-conditioning desiccant application.

DESICCANT LIFE

The useful life of desiccant materials depends largely on the quantity and type of contamination in the airstreams they dry. In commercial equipment, desiccants last between 10,000 and 100,000 h and longer before they need replacement.



The sources for isotherms presented in the figure include :
PSSASS: Solar Energy Research Insitute Report No. PR-255-3308
Lithium chloride: Cargocaire Engineering Division of Munters USA and Kathabar Systems Division of Sommerset Technologies
Triethylene glycol: Dow Chemical Corporation
Silica gel: Davison Chemical Division of W.R. Grace Co. Inc.
Activated carbon: Calgon Corporation
Activated alumina: LaRoche Chemical Company
Molecular sieve: Davison Chemical Division of W.R. Grace Co.

Fig. 7 Sorption Isotherms of Various Desiccants at 72 °F

Normally, two mechanisms cause the loss of desiccant capacity—change in desiccant sorption characteristics through reactions with contaminants, and loss of effective surface area through clogging or hydrothermal degradation. Liquid absorbents are more susceptible to chemical reaction with airstream contaminants other than water vapor than are solid adsorbents. For example, certain sulfur compounds can react with lithium chloride to form lithium sulfate, which is not a desiccant. If the concentration of such compounds in the airstream were below 10 ppm and the desiccant were in use 24 h a day, the capacity reduction would be approximately 10 to 20% after three years of operation. If the concentration were 30 ppm, the capacity change would occur after one year.

Adsorbents tend to be less reactive chemically and more sensitive to clogging, a function of the type and quantity of particulate material in the airstream. In some situations, certain adsorbents are sensitive to hydrothermal stress, resulting from the

thermal expansion and contraction of the desiccant material on rapid changes in desiccant moisture content. For example, silica gel that must move between an airstream above 95% rh at low temperatures and a reactivating airstream at high temperatures six times per hour, 24 h a day can partly fracture; this may mean a 10% reduction in capacity over the course of a year.

In air-conditioning applications, desiccant equipment is designed to minimize the need for desiccant replacement in much the same way that vapor compression cooling systems are designed to avoid the need for compressor replacement. Unlike filters, desiccants are seldom intended to be frequently replaced during normal service in an air-drying application.

COSORPTION OF WATER VAPOR AND INDOOR CONTAMINANTS

Hines *et al.* (1991) have confirmed that many desiccant materials can collect common indoor pollutants at the same time they collect water vapor from ambient air. This characteristic promises to become useful in future air-conditioning systems where the quality of indoor air is especially important.

The behavior of different desiccant and different vapor mixtures is complex but, in general, pollutant absorption reactions can be classified into five categories:

- Humidity-neutral sorption
- Humidity-reduced sorption
- Humidity-enhanced sorption
- Humidity-pollutant displacement
- Desiccant-catalyzed pollutant conversion

An example of humidity-reduced sorption is illustrated by the behavior of water vapor and chloroform on activated carbon. Sorption is humidity-neutral until relative humidity exceeds 45%, when the uptake of chloroform is reduced. The adsorbed water blocks sites that would otherwise attract and hold chloroform. In contrast, water and carbonyl chloride mixtures on activated carbon demonstrate humidity-enhanced sorption. Here, sorption of the pollutant increases at high relative humidities. Hines *et al.* (1991) attribute this phenonmenon to the high water solubility of carbonyl chloride.

PROPER design of space heating, air conditioning, refrigeration systems, and other industrial applications requires knowledge of thermal insulations and thermal behavior of building structures. This chapter deals with heat and moisture transfer definitions, fundamentals and properties of thermal insulation materials, heat flow calculations, economic thickness of insulation, and the fundamentals of moisture as it relates to building components and systems.

DEFINITIONS AND SYMBOLS

The following heat and moisture transfer definitions and symbols cover common building industry terms. The units used in the definitions are in I-P units: British thermal units (Btu), hour (h), temperature (°F), absolute temperature (R), temperature difference (°F), feet (ft), inches (in.), pound (lb), grains (gr), and inches of mercury (in. Hg).

Thermal transmission, heat transfer, or **rate of heat flow.** The flow of heat energy induced by a temperature difference. Heat may be transferred by conduction, mass transfer, convection, and radiation. These can occur separately or in combinations, depending on specific circumstances.

Thermal conductivity, k. The time rate of heat flow through a unit area of homogeneous material in a direction perpendicular to isothermal planes induced by a unit temperature gradient. (ASTM *Standard* C168 defines homogeneity.) Units are Btu · in/h · ft² · °F or Btu/h · ft · °F (if thickness is in ft). Thermal conductivity must be evaluated for a specific mean temperature, because in most materials it varies with temperature.

For many thermal insulation materials, heat flows by a combination of modes and may depend on orientation, direction, or both. The measured property of such materials may be called *effective* or *apparent* thermal conductivity. The specific test conditions, *i.e.*, sample thickness, orientation, environment, environmental pressure, surface temperature, mean temperature, and temperature difference, should be reported with the values. With thermal conductivity, the symbol k_{app} is used to note the lack of pure conduction or to state that all values reported are apparent.

Thermal resistivity, R_u. Reciprocal of thermal conductivity. Units are °F · ft² · h/(Btu · in).

Thermal conductance, C-factor, C. Time rate of heat flow through a unit area of a body induced by a unit temperature difference between the body surfaces, Btu/h · ft² · °F.

When the two defined surfaces of mass-type thermal insulation have unequal areas, as in the case of radial heat flow through a curved block or through a pipe covering (see Chapter 3, Table 2) or through materials of nonuniform thickness, an appropriate mean area and mean thickness must be given. Heat flow formulas involving materials that are not uniform slabs must contain *shape factors* to account for the area variation involved.

When heat flow is by conduction alone, thermal conductance of a material may be obtained by dividing the thermal conductivity of the material by its thickness. When several modes of heat transfer are involved, the *apparent* or *effective* thermal conductance may be obtained by dividing the apparent thermal conductivity by the thickness.

Where air circulates within or passes through insulation, as it may with low-density fibrous materials, the effective thermal conductance is affected.

Thermal conductances and thermal resistances of the more common building materials and industrial insulations are tabulated in Chapter 22.

Heat transfer film coefficient (surface coefficient of heat transfer, surface film conductance), h or f. Heat transferred between a surface and a fluid in unit time through unit area induced by unit temperature difference between the surface and the fluid in contact with it, Btu/h · ft² · °F.

Surface film resistance. The reciprocal of the heat transfer film coefficient, °F · ft² · h/Btu.

Note 1: The surrounding space must be air or other fluids for radiation or convection or both to take place. If space is evacuated, the only heat flow is by radiation.

Note 2: Subscripts i and o often denote inside and outside surface resistances and conductances, respectively.

Thermal resistance, R. Under steady conditions, the mean temperature difference between two defined surfaces of material or construction that induces unit heat flow through a unit area, °F · ft² · h/Btu.

Thermal transmittance, U-factor, U. The time rate of heat flow per unit area under steady conditions from the fluid on the warm side of a barrier to the fluid on the cold side, per unit temperature difference between the two fluids. It is evaluated by

The preparation of this chapter is assigned to TC 4.4, Thermal Insulation and Moisture Retarders.

first evaluating the R-value and then computing its reciprocal, U, in Btu/h · ft² · °F.

Note 1: The U-factor is sometimes called the overall coefficient of heat transfer.

Note 2: In building practice, the heat transfer fluid is air. The temperature of the fluid is obtained by averaging its temperature over a finite region of the fluid near the surface involved.

Thermal emittance, ϵ. The ratio of the radiant flux emitted by a body to that which would be emitted by a blackbody at the same temperature and under the same conditions.

Note: Effective emittance E is the combined effect of emittances from the boundary surfaces of an air space, where the boundaries are parallel and of a dimension much larger than the distance between them. Chapter 22 lists values of E for various air spaces.

Surface reflectance, ρ. The fraction of the radiant flux falling on a surface that is reflected by it.

Water vapor permeability, μ. The property of a substance that permits passage of water vapor. When permeability varies with psychrometric conditions, the spot or specific permeability defines the property at a specific condition in gr/h · ft² · (in. Hg/in.), where in. Hg is vapor pressure difference.

Water vapor permeance, ***M.*** The rate of water vapor transmission per unit area of a body between two specified parallel surfaces, to the vapor pressure difference between the two surfaces, gr/h · ft² · in. Hg.

The perm is a widely used measure of water vapor transmission rate in gr/h · ft² · in. Hg. Originally, 1 perm was proposed as the maximum allowable permeance for a vapor retarding component to ensure a low probability for moisture problems in building construction. The perm was intended to apply to houses in climates that do not exceed 5000 °(heating) degree days (Fahrenheit) of cold weather. Thus the word "perm", as originally defined, has a very specific and limited meaning.

Water vapor resistance, ***RV.*** The reciprocal of permeance—signifies a resistance to moisture flow (in. Hg · ft² · h/gr). A *rep* is a unit resistance to water vapor flow, *i.e.*, rep = 1/perm.

THERMAL INSULATION

Thermal insulations are materials or combinations of materials that, when properly applied, retard the flow of heat energy by conductive, convective, and/or radiative transfer modes. These materials can be fibrous, particulate, film or sheet, block or monolithic, open or closed cell, or composites of these materials that can be chemically or mechanically bound or supported.

By retarding heat flow, thermal insulations can serve one or more of the following thermal functions:

1. Conserve energy by reducing heat loss or gain of piping, ducts, vessels, equipment, and structures.
2. Control surface temperatures of equipment and structures for personnel protection and comfort.
3. Help control the temperature of a chemical process, a piece of equipment, or a structure.
4. Prevent vapor condensation on surfaces with a temperature below the dew point of the surrounding atmosphere.
5. Reduce temperature fluctuations within an enclosure when heating or cooling is not needed or available.
6. Reduce temperature variations within a conditioned space for increased personal comfort.
7. Provide fire protection.

Thermal insulation can serve additional functions, although such secondary functions should be consistent with its capabilities and primary purpose. Under certain conditions, insulations may:

1. Add structural strength to a wall, ceiling, or floor section.
2. Provide support for a surface finish.
3. Impede water vapor transmission and air infiltration.
4. Prevent or reduce damage to equipment and structures from exposure to fire and freezing conditions.
5. Reduce noise and vibration.

Thermal insulation is used to control heat flow at all temperatures, the limiting value being its survival temperature.

BASIC MATERIALS

Thermal insulations normally consist of the following basic materials and composites:

- Inorganic, fibrous, or cellular materials such as glass, rock, or slag wool; calcium silicate, bonded perlite, vermiculite, ceramic products; and asbestos. Asbestos has been shown to be a carcinogen. Extreme caution must be used if it is encountered.
- Organic fibrous materials such as cotton, animal hair, wood, pulp, cane, or synthetic fibers, and organic cellular materials such as cork, foamed rubber, polystyrene, polyurethane, and other polymers.
- Metallic or metallized organic reflective membranes. These surfaces must face air, gas-filled, or evacuated spaces to be effective.

PHYSICAL STRUCTURE AND FORM

Mass-type insulation can be cellular, granular, or fibrous solid material to retard heat flow. Reflective insulation consists of smooth-surfaced sheets of metal foil or foil-surfaced material separated by air spaces.

The physical forms of industrial and building insulations include the following:

Loose-fill insulation consists of fibers, powders, granules, or nodules that are usually poured or blown into walls or other spaces.

Insulating cement is a loose material mixed with water or a suitable binder to obtain plasticity and adhesion. It is troweled or blown wet on a surface and dried in place. Both loose-fill and insulating cement are suited for covering irregular spaces.

Flexible and semirigid insulations consist of organic and inorganic materials with and without binders and with varying degrees of compressibility and flexibility. These insulations are generally available as blanket, batt, or felt insulation, and in either sheets or rolls. Coverings and facings may be fastened to one or both sides and serve as reinforcing; air or vapor retarders or both; reflective surfaces; or surface finishes. These coverings include combinations of laminated foil, glass, cloth or plastics and paper, wire mesh, or metal lath. Although standard sizes are generally used, thickness and shape of insulation can be any dimension handled conveniently.

Rigid materials are available in rectangular blocks, boards, or sheets, which are preformed during manufacture to standard lengths, widths, and thicknesses. Insulation for pipes and curved surfaces is supplied in sections or segments, with radii of curvature available to suit all standard sizes of pipe and tubing; it is also supplied in greater diameters.

Reflective materials are available in sheets and rolls of single layer or multilayer construction and in preformed shapes with integral air spaces.

Formed-in-place insulations are available as liquid components or expandable pellets that can be poured, frothed, or sprayed in place to form rigid or semirigid foam insulation. Fibrous materials mixed with liquid binders can also be sprayed in place, and in some products, the binder is also a foam.

Accessory materials for thermal insulation include mechanical and adhesive fasteners, exterior and interior finishes, vapor and air retarder coatings, jackets and weather coatings, sealants, lagging adhesives, membranes, and flashing compounds. ASTM *Standard* C168 defines terms relating to thermal insulating materials.

PROPERTIES

Thermal insulation selection may involve secondary criteria in addition to the primary property of low thermal conductivity. Characteristics such as resiliency or rigidity, acoustical energy absorption, water vapor permeability, airflow resistance, fire hazard and fire resistance, ease of application, applied cost, health and safety aspects, or other parameters may influence the choice among materials that have almost equal thermal performance values.

Thermal

Thermal resistance is a measure of the effectiveness of thermal insulation's ability to retard heat flow. Material with a high thermal resistance (low thermal conductance) is an effective insulator.

Heat transmission in most thermal insulations is accomplished by a combination of gas and solid conduction, radiation, and convection. Heat transfer through materials or systems is controlled by factors such as length of heat flow paths, temperature, temperature difference characteristics of the system, and environmental conditions.

Although heat transmission characteristics are usually determined by measuring thermal conductivity, this property does not strictly apply to thermal insulation. A particular sample of a material has a unique value of thermal conductivity for a particular set of conditions. This value may not be representative of the material at other conditions and should be called *apparent* thermal conductivity. For details, refer to ASTM *Standards* C168, C177, C236, C335, C518, C691, and C976.

Reflective insulations impede radiant heat transfer because the surfaces have high reflectance and low emittance values. (Chapter 22, Table 1, gives typical design values.) To be effective, the reflective face of both single and multiple layer reflective insulations must face an air or evacuated space. Multiple layers of reflective materials and smooth and parallel sealed air spaces increase overall thermal resistance. Air exchange and movement must be inhibited.

Mass-type insulation can be combined with reflective surfaces and air spaces to obtain a higher thermal resistance. However, each design must be evaluated since maximum thermal performance of these systems depends on such factors as condition of the insulation, shape and form of the construction, the means to avoid air leakage and movement, and the condition of the installed reflective surfaces and their aging characteristics.

Design values of effective or apparent thermal conductivity, thermal conductance, and thermal resistance for the most common insulations are listed in Table 4, Chapter 22. These values have been selected as typical and useful for engineering calculations. The manufacturer or test results of the insulation under appropriate conditions can give values for a particular insulation.

Other thermal properties that can be important are specific heat, heat capacity, thermal diffusivity, the coefficient of thermal expansion, and maximum temperature limit. *Heat capacity* is the product of specific heat and mass. *Thermal diffusivity* becomes important for applications where temperature varies with time, since the rate of temperature change within an insulation is proportional to its thermal diffusivity for a given thickness. Chapter 3 covers symbols, definitions, and methods of calculation in steady-state heat transfer.

Mechanical

Some insulations have sufficient structural strength for load bearing. They are used occasionally to support load-bearing floors, form self-supporting partitions, or stiffen structural panels. For such applications, one or more of the following properties of an insulation may be important: strength in compression, tension, shear, impact, flexure, and resistance to vibration. These temperature-dependent mechanical properties vary with basic composition, density, cell size, fiber diameter and orientation, type and amount of binder (if any), and temperature and environmental conditioning.

Health and Safety

Most thermal insulations have good resistance to fire, vermin, rot, objectionable odors, and vapors; some are a potential risk to health and safety. These risks can result from direct exposure to these materials and accessories while they are being stored or transported, during or after installation, or as a result of intervening or indirect actions or events, such as aging, fire, or physical disturbance. The potential health and safety effects of thermal insulation can be considered in two categories: (1) those related to storage, handling, and installation operations and (2) those that occur after installation (such as aging). Potential hazards during manufacture are not discussed. Correct handling, installation, and precautionary measures can reduce or eliminate these problems.

Potential health effects range from temporary irritation to serious changes in body functions. The principal concerns are with insulation containing asbestos. Questions have also been raised about man-made fibers. To date, research is inconclusive as to their potential hazard; however, they can be very annoying in installation, and the use of proper safeguards is desirable. Potential traumatic injury can occur during or from direct contact with materials that are sharp, rough, have protrusions or abrasive surfaces, permit overheating, or transmit electrical energy.

Combustion of insulation materials and accessories may release heat, hazardous gases, fibers, and particulates. Manufacturers' recommendations and applicable government codes and standards (ASTM *Standard* C930) have more details.

Acoustics

Some thermal insulations are used as acoustical control materials, whether or not thermal performance is a design requirement. Acoustical efficiency depends on the physical structure of the material. Materials with open, porous surfaces have sound absorption capability. Those of high density and resilient characteristics can act as vibration insulators; either alone or in combination with other materials, some are an effective barrier to sound transmission. Insulations for sound conditioning include flexible and semirigid, formed-in-place fibrous materials, and rigid fibrous insulation.

Sound absorption insulations are normally installed on interior surfaces or used as interior surfacing materials. Rigid insulations are fabricated into tile or blocks, edge-treated to facilitate mechanical or adhesive application, and prefinished during manufacture. Some insulation units have a natural porous surface, others include mechanical perforations to facilitate the entry of sound waves, and still others use a diaphragm or decorative film surfacing attached only to the edges of the units, which allows the sound waves to reach the fibrous backing by diaphragm action.

Flexible, semirigid, and formed-in-place fibrous materials used for sound absorption are available in a variety of thicknesses and densities that determine their sound absorption characteristics.

When density is increased by reducing the thickness of the material, sound absorption is generally reduced; however, as thickness increases, the influence of density is minimal.

Thermal insulations improve sound transmission loss when installed in *discontinuous construction*. A wall of staggered stud construction that uses resilient clips or channels on one side of the stud or resilient insulation boards of special manufacture to prevent acoustical coupling mechanically between the surfaces reduces sound transmission. A sound absorption thermal insulation blanket in a wall cavity reduces sound transmission, depending on the type of construction.

In floor construction, resilient channels or separate floor and ceiling joists form a discontinuous construction; thermal insulation placed within this construction further reduces sound transmission. Sound-deadening boards underlying finish flooring absorb impact sounds and improve the airtightness of the construction, thus reducing airborne sound transmission.

Thermal insulation boards can be placed under mechanical equipment to isolate vibration. The imposed loading and natural resonant frequency of materials are critical for proper design. Since material must deflect properly under load to provide isolation, the system should be neither overloaded nor underloaded.

For further information on sound and vibration control, refer to Chapter 42 of the 1991 ASHRAE *Handbook—HVAC Applications.*

Other Properties

Other properties of insulating materials that can be important, depending on the application, include density, resilience, resistance to settling, permanence, reuse or salvage value, ease of handling, dimensional uniformity and stability, resistance to chemical action and chemical change, resistance to moisture penetration, ease in fabrication, applying of finishing, and sizes and thicknesses obtainable.

HEAT FLOW

FACTORS AFFECTING THERMAL PERFORMANCE

A wide variety of physical, environmental, application, and, in some cases, aging factors affect the thermal performance of insulations.

Thermal conductivity k is a property of a homogeneous material. Building materials, such as lumber, brick, and stone, are usually considered homogeneous. Most thermal insulation, except some reflective types, is porous and consists of combinations of solid matter with small voids.

For most insulating materials, conduction is not the only mode of heat transfer. Consequently, the term *apparent thermal conductivity* describes the heat flow properties of most materials. Some materials with low thermal conductivities are almost purely conductive (silica opacified aerogel, corkboard, etc.).

The apparent thermal conductivity of insulation varies with form and physical structure, environment, and application conditions. Form and physical structure vary with the basic material and manufacturing process. Typical variations include density, cell size, diameter and arrangement of fibers or particles, degree and extent of bonding materials, transparency to thermal radiation, and the type and pressure of gas within the insulation.

Environment and application conditions include mean temperature, temperature gradient, moisture content, air infiltration, orientation, and direction of heat flow. Thermal performance values for insulation materials and systems are usually obtained by standard methods listed in Volume 04.06 of the *Annual Book of ASTM Standards*. The methods apply mainly to laboratory measurements on dried or conditioned samples at specific mean temperatures and temperature gradient conditions. Although the fundamental heat transmission characteristics of a material or system can be determined accurately, actual performance in a structure may vary from that indicated in the laboratory due to application variations. Field measurement techniques continue to be developed. The design of the envelope, its construction, and the materials used may all affect the test procedure. These factors are detailed in ASTM STP 544-74, STP 660-79, STP 718-80, ASTM STP 789-83, ASTM STP 879-86, STP 885-85, and STP 922-88.

The effective thermal conductivity of some thermal insulation materials varies with density. Figure 1 illustrates this variation at one mean temperature for a number of materials currently used to insulate building envelopes. For most mass insulations, there is a minimum in the respective apparent thermal conductivity versus density. This minimum depends on the type and form of material, temperature, and direction of heat flow. For fibrous materials, the values of density at which the minimum value occurs increase as both the fiber diameter or cell size and the mean temperature increase. These effects are shown in Figures 2 (Lotz 1969) and 3, respectively.

Other factors that affect thermal performance include compaction and settling of insulation, type and amount of binder used, additives that may influence the bond or contact between fibers or particles, and, if used, type and form of radiation transfer inhibitor. In cellular materials, the factors that influence thermal performance and strength properties are the same as those that control the thermal conductivity of the basic structured material: size and shape of the cells, thickness of the cell walls, gas contained in the cells, orientation of the cells, and radiation characteristics of the cell surfaces.

A change in density caused by the degree of compaction of insulation of powders affects the effective thermal conductivity. Insulating concretes made from lightweight aggregates can be produced in a wide range of densities, with corresponding thermal conductances.

Fibrous insulations reach a minimum conductivity when fibers are uniformly spaced and perpendicular to the direction of heat flow. Generally, a decrease in the diameter of the fiber lowers the

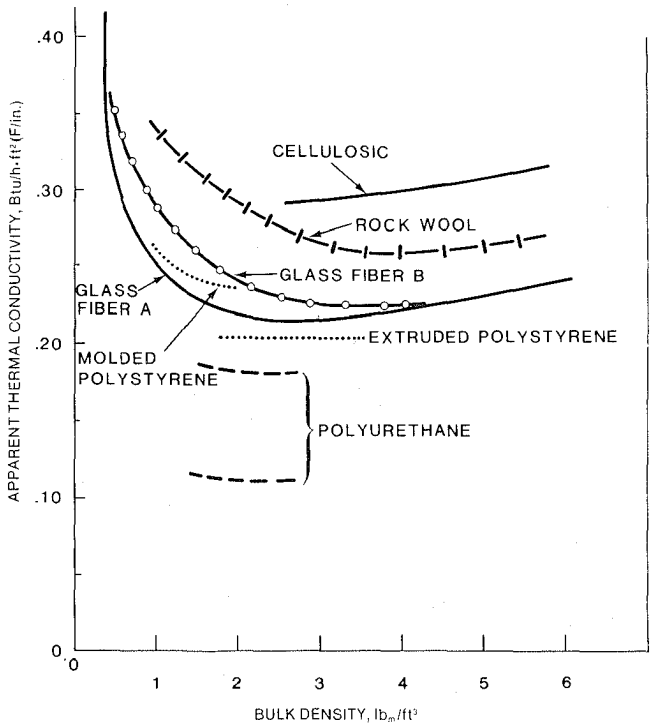

Fig. 1 Apparent Thermal Conductivity versus Density of Several Thermal Insulations Used as Building Insulations

conductivity for the same density (Figure 2). For cellular insulation, a specific combination of cell size, density, and gas composition produces optimum thermal conductivity.

At temperatures below 400 to 570 °F, the greater portion of heat transfer across most insulations occurs by conduction through the air or through other gas in the insulations (Rowley *et al.* 1952, Lander 1955, Simons 1955, Verschoor and Greebler 1952). Consequently, if the gas within the insulation is replaced by another gas with a different thermal conductivity, the apparent thermal conductivity of the insulation is changed by an amount approximately equal to the difference in conductivity of the two gases. For example, replacing air with a fluorinated hydrocarbon gas can lower the apparent thermal conductivity of the insulation by as much as 50%. Fluorocarbon-expanded cellular plastic foams with a high proportion (greater than 90%) of closed cells retain the fluorocarbon within the cells for extended periods. As these products are initially produced, they have apparent thermal conductivities of approximately 0.111 Btu/h·ft²·(°F/in) at 75 °F when the gas contained has a mean-free-path greater than the dimensions within the cells. However, this value increases with time as atmospheric gases diffuse into the cells and the fluorocarbon gas diffuses out. The rates of diffusion and increase in apparent thermal conductivity depend on several factors, including permeance of the cell walls to the gases involved, age of the foam, temperature, geometry of the insulation (thickness), and surface protection provided. The significance of the surface is apparent when foams are encased in gas-impermeable membranes or some water vapor retarders (Brandreth 1986, Tye 1987).

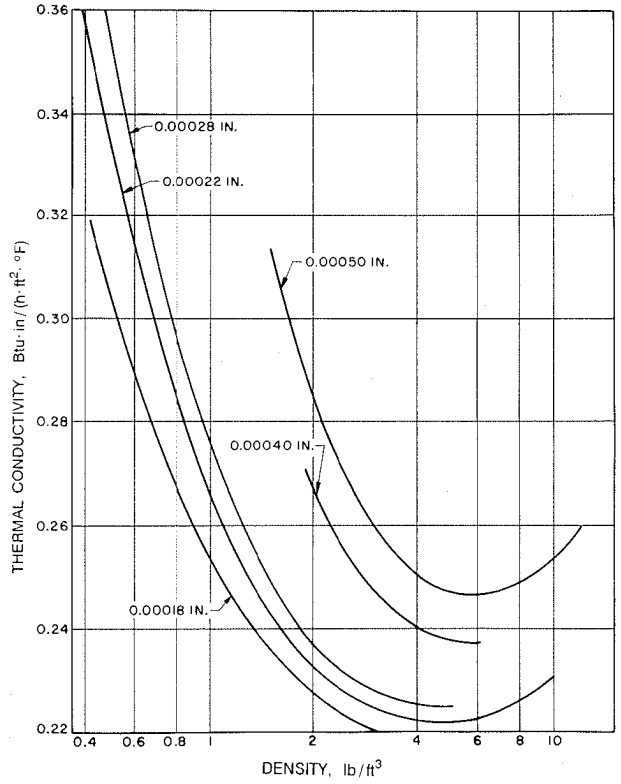

Fig. 2 Typical Variation of Apparent Thermal Conductivity with Fiber Diameter and Density (Heat Flow Perpendicular to Fiber Orientation)

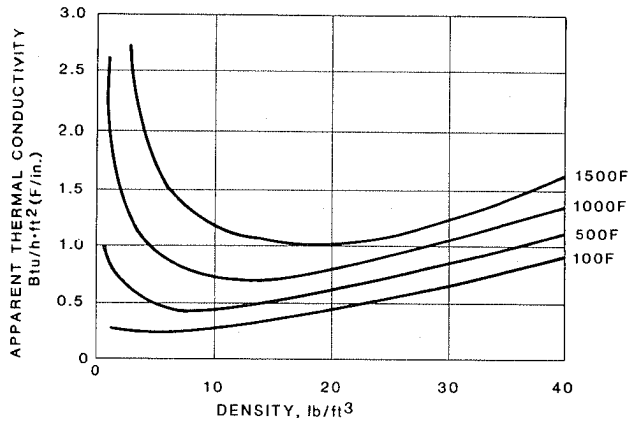

Fig. 3 Typical Variation of Apparent Thermal Conductivity with Mean Temperature and Density

For polyurethane and polyisocyanurate materials, Brandreth (1986) and Tye (1988) show that the aging process of these materials is reasonably well understood analytically and confirmed experimentally. The dominant parameters for minimum aging are as follows:

- closed-cell content > 90% preferably > 95%
- small uniform cell diameter << 0.04 in.
- small anisotropy in cell structure
- low density (1.8 to 3 lb/ft³)
- increasing thickness
- high initial pressure of fluorocarbon blowing agent in cell
- a polymer highly resistant to gas diffusion and solubility
- polymer distributed evenly in struts and windows of the cell
- a low aging temperature

Aging may be further reduced, particularly for laminated and spray-applied products with higher density polymer skins, or by well-adhered facings and coverings with low gas and moisture permeance characteristics. An O_2 diffusion rate of less than 0.02 in³/1000 ft²·day for 0.001 in. thickness of barrier is one criterion used by some industry organizations manufacturing laminated products. The adhesion of any facing must be continuous, and every effort must be made in the manufacturing process to eliminate or minimize the shear plane layer at the foam/substrate interface (Ostrogorsky and Glicksman 1986).

Closed-cell phenolic-type materials and products, while blown with similar gases, age differently and much more slowly. The reasons for this are under study, but higher material density, smaller, more uniform cell size with more even distribution of polymer in struts and windows, and a basic polymer more resistant to gas diffusion could be contributory causes.

The average distance, or *mean-free-path*, that an enclosed gas molecule travels before striking another gas molecule increases as pressure within an insulation decreases. When the mean-free-path equals the average distance a gas molecule travels before striking a solid part of the insulation, apparent thermal conductivity of the insulation decreases with decreasing pressure. Correspondingly, for materials such as silica gel and fine carbon black, which have an average pore size smaller than the mean-free-path of air at atmospheric pressure, it is possible to attain thermal conductivity values lower than those for still air (Verschoor and Greebler 1952).

For homogeneous, dense materials, the primary mode of heat transfer is conduction. However, as the temperatures and the consequent transparency of materials increase, the heat transmission by thermal radiation and possible convection becomes a greater part of the total heat transferred. The magnitude of radiation and convection transfer depends on temperature difference, direction of heat flow, the nature of materials involved, and geometric considerations. The rate of radiant heat transfer varies in proportion to the fourth power of the absolute temperature.

Because of radiation heat transfer in low-density insulation, measured apparent thermal conductivity depends on test thickness. The thickness effect increases the apparent thermal conductivity measured at installed thickness over that commonly determined at 1 in. (Pelanne 1979). From a thermal resistance standpoint, the effect is small, typically less than 10% for most 1- to 6-in. thick insulations.

Environment and Application Conditions

The apparent conductivity of insulating materials generally increases with temperature. Figure 4 shows typical variations with mean temperature. However, some materials, such as fluorocarbon-expanded, closed-cell urethanes, have an inflection in the curve over the temperature range where there is a change of phase of the fluorocarbon from gas to liquid (see Table 4, Chapter 22).

The apparent thermal conductivity of a sample at one mean temperature (average of the two surface temperatures) only applies to the material at the particular thickness tested. Further testing is required to obtain values suitable for all thicknesses. The rate of change of apparent thermal conductivity with temperature and environmental conditions varies with the type and density of material.

Insulating materials that permit a large percentage of heat transfer by radiation, such as low-density fibrous and cellular products, show the greatest change in apparent thermal conductivity with changes of temperature and surrounding surface emittance. The ASTM Standard Test Methods recognize the importance of radiation in heat transmission and require that the surfaces of all plates be painted or otherwise treated to have a total emittance greater than 0.8 at operating temperature.

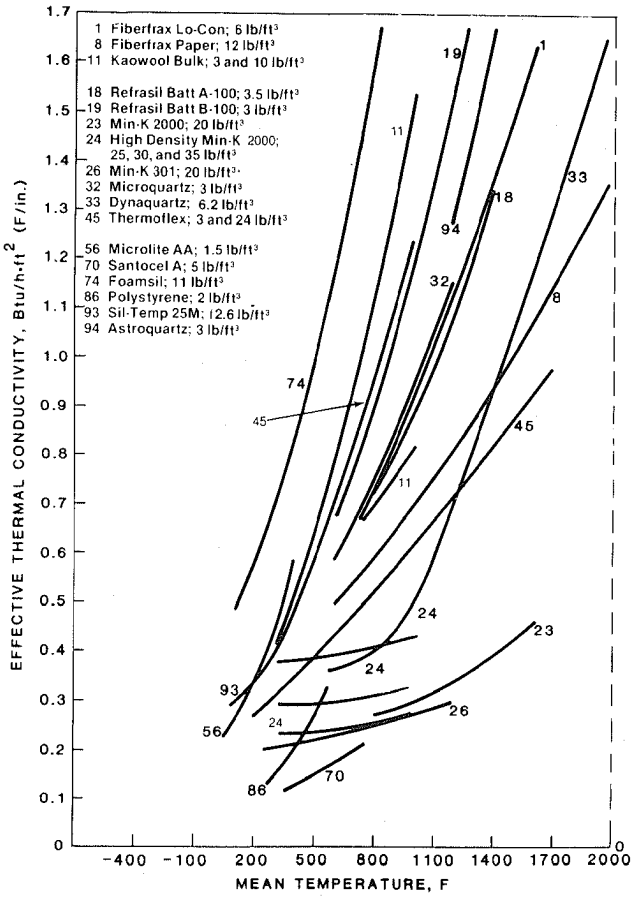

Fig. 4 Apparent Thermal Conductivity versus Mean Temperature for Various Materials (in Air at Atmospheric Pressure)
(Glaser *et al.* 1967, Pelanne 1977)

The effect of temperature alone on structural integrity is not ordinarily important for most materials in the low-temperature insulation field. Decomposition, excessive linear shrinkage, softening, or some other effects of temperature alone limit the maximum temperature for which a material is suited. At extreme temperatures, both high and low, selecting materials for a specific service becomes more critical and must be based on experience and factual performance data (see Table 4, Chapter 22).

Convection and air infiltration in or through some insulation systems, may increase heat transfer across them. Low-density, loose-fill, large open-cell and fibrous insulations, and poorly designed or installed reflective systems are most susceptible to increased heat transfer by air filtration and forced convection or both. The temperature difference across an insulation, as well as the height, thickness, or width of the insulated space, influences the amount of convection. In some cases, natural convection may be inherent in the systems (Wilkes and Rucker 1983); however, in many cases, the effect of convection in or through insulation can be minimized by careful design of an insulated structure (Donnelly *et al.* 1976).

Gaps between both board- and batt-type insulation can lower insulation effectiveness. Board-type insulation may not be perfectly square, it may be installed improperly, and the surfaces to which it is applied may be uneven. Joints formed in board-type insulation allow it to fit together without air gaps. Batts can be installed in two layers with joints between layers offset and staggered. For example, a 4% void area around batt insulation can produce a 30% loss in effective thermal resistance for an R-19 ceiling application (Verschoor 1977). Similar results have been obtained with different test conditions and for wall configurations (Lewis 1979, Hedlin 1985, Tye *et al.* 1981). Chapter 21 has further details on these effects.

If moisture condenses in the insulation, it may reduce thermal resistance, and, perhaps physically damage the system. The reduction in thermal resistance depends on the material, the moisture content, and its distribution. The thermal characteristics of some insulations may be affected at 0% moisture content (Tobiasson *et al.* 1977, Tye *et al.* 1987).

Verschoor (1985) showed that an insulated residential-type stud wall panel with a poor vapor retarder on the warm side accumulated 0.3 lb of moisture per square foot when exposed to continuously below freezing (steady-state) conditions for 31 days. All of the accumulated moisture was located in the 0.5-in. layer of mineral fiber insulation immediately adjacent to the exterior cold side sheathing and at the interface between the insulation and the sheathing. In a continuation of the test program, when the total exposure period was 60 days, the rate of moisture gain remained constant during the entire period. Subsequently, the same test wall was subjected to diurnal outside temperature cycles through the freezing point. With this exposure, most of the accumulated moisture was found in the sheathing and the bottom of the test wall rather than in the coldest insulation layer. Except for the sheathing, there was negligible change in the overall thermal performance of the wall.

The behavior may be different for closed-cell plastic foam insulations. Field observations of low-temperature insulated tanks have shown that when no air space exists between the cold surface and the insulation, the expected accumulation of condensed moisture did not occur.

Because the thermal conductivities of water and ice are many times greater than that of the gas they displace in insulation, their presence in insulation systems can have a markedly deleterious effect. This is detailed in the section Effect of Moisture on Heat Flow. CIBSE *Guide*, Section A3 (1986) and Chapter 21 cover the thermal properties of building structures affected by moisture.

THERMAL TRANSMITTANCE

The method of calculating an overall coefficient of heat transmission requires knowledge of (1) the apparent thermal conductivity and thickness of homogeneous components, (2) thermal conductance of nonhomogeneous components, (3) surface conductances of both sides of the construction, and (4) conductance of air spaces in the construction. Procedures for calculating thermal conductance and resistance and definitions of heat transfer terms and symbols are included in this chapter and in Chapter 3. In some construction, multidimensional heat flow effects are significant. Parallel heat flow paths of different resistances occur in wood frame house construction, for example. In such cases, the guarded hot box method (ASTM C236) or the calibrated hot box method (ASTM C976) may be used to determine overall thermal transmittance.

Surface Conductance

Surface conductance is the heat transfer to or from the surface by the combined effects of radiation, convection, and conduction. Each of these transport modes can vary independently. Heat transfer by radiation between two surfaces is controlled by the character of the surfaces (emittance and reflectivity), the temperature difference between them, and the solid angle through which they see each other. Heat transfer by convection and conduction is controlled by surface roughness, air movement, and temperature difference between the air and surface. Table 1 illustrates the importance of the effect of temperature of surrounding surfaces on surface heat flux caused by radiation.

In many cases, because the thermal resistance (reciprocal of conductance) of the internal parts of the wall is high compared with the surface resistance, the surface factors are of minor importance. However, surface resistances on a window with a single pane of glass constitute almost the entire resistance and are very important. Raber and Hutchinson (1945) analyzed the factors affecting surface conductance and the difference between surface and air temperatures.

The convective part of the surface conductance is markedly affected by the nature of the air movement on the surface, illustrated by Figure 1, Chapter 22. On smooth surfaces, surface length (Parmelee and Huebscher 1947) also affects the convection part of conductance; the average value decreases as the surface length increases. Moreover, observations (Parmelee and Aubele 1950) of the magnitude of low-temperature radiant energy from outdoor surroundings show that only under certain conditions can outdoors be treated as a blackbody radiating at an effective air temperature. Therefore, selection of surface conductance coefficients for a building becomes a matter of judgment. Surface conductances shown in Table 1 of Chapter 22 are applicable to ordinary building materials. In special cases, where surface conductances become important factors in the overall rates of heat transfer, more accurate coefficients may be required. Principles and data given in Chapter 3 can be applied in such cases.

FACTORS AFFECTING HEAT TRANSFER ACROSS AIR SPACES

The nature of the boundary surfaces, as well as the intervening air space, the orientation of the air space, and the direction of heat flow, affect the transfer of heat across an air space. Air space conductance coefficients represent the total conductance from one surface bounding the air space to the other. The total conductance is the sum of a radiation component and a convection and conduction component. In all cases, the spaces are considered airtight with no through air leakage.

Table 1 Variation in Surface Heat Flux for Vertical Surfaces at 80 °F with Different Temperatures of Surrounding Surface (70 °F Ambient Still Air; 0.83 Emittance)

Surrounding Surface Temperature, °F	Surface Heat Flux, Btu/h·ft²				
	75	70	65	60	50
Convection	6.6	6.6	6.6	6.6	6.6
Radiation	4.4	8.6	12.8	17.0	24.9
Total	11.0	15.2	19.4	23.6	31.5

The radiation portion of the coefficient is affected by the temperature of the two boundary surfaces and by their respective surface properties. For surfaces that can be considered ideal graybodies, the surface properties can be characterized by emissivity. The combined effect of the emittances of the boundary surfaces of an air space is expressed by the effective emittance E of the air space. The radiation component is unaffected by the thickness of the space, its orientation, the direction of heat flow, or the order of emittance (hot or cold surface). The heat transfer by convection and conduction combined is affected markedly by orientation of the air space and the direction of heat flow, by the temperature difference across the space, and, in some cases, by the thickness of the space. It is also slightly affected by the mean temperature of its surfaces. For air spaces in building construction, the radiation and convection-conduction components can vary independently of each other.

Table 2, Chapter 22 lists the thermal resistance values of sealed air spaces of uniform thickness and moderately smooth, plane, parallel surfaces. These data are based on experimental measurements (Robinson *et al.* 1954). Resistance values for systems with air spaces can be estimated from these results if emissivity values are corrected for field conditions. However, the value of some common composite building insulation systems involving mass-type insulation with a reflective surface in conjunction with an air space may be appreciably lower than the estimated value (Palfey 1980), particularly if the air space is not sealed or of uniform thickness. The thermal resistance values for plane air spaces in Table 2 of Chapter 22 represent typical values; for critical applications, the effectiveness of a particular design should be confirmed by actual test data undertaken by using ASTM hot box methods. This test is especially necessary for constructions combining reflective and nonreflective thermal insulation.

For narrow air spaces, defined as those for which the product of the temperature difference (in degrees Fahrenheit) and the cube of the space thickness (in inches) is less than 3 for heat flow horizontally or downward, or less than 1 for heat flow upward, convection is practically suppressed. The conductance for these spaces is the sum of the radiative heat transfer coefficient and that for heat conduction alone through air. The radiation and conduction component can be computed by the method shown in the footnote to Table 2, Chapter 22. Effects of different mean temperatures, temperature differences, and effective emittances may be found in Table 2 of Chapter 22.

To obtain high thermal resistance with reflective insulation, a series of multiple air layers bounded by reflective surfaces is needed. The total resistance equals the sum of the resistance values across each air space. All air layers or spaces must be sealed because air moving between the layers can increase the heat flow. Depending on the type of reflective insulation, one or both sides may have highly reflective surfaces. Except for thick horizontal air spaces with heat flow down, little is gained thermally by the addition of a second highly reflective surface to the same air space. If an air space has only one reflective surface, the side on which the reflective surface is placed makes no appreciable difference in the rate of heat transfer; however, placing the surface on the warm side minimizes or prevents condensation. Condensation should

be prevented from forming on a reflective surface because, apart from other effects, it degrades the reflective properties of the surface. A reflective surface placed on the warm side of an air space usually is not a condensing surface and, therefore, maintains the thermal resistance of the air space and acts as a water vapor retarder if the material and its joints are low in permeance (see discussion on vapor retarders).

The emittance of a surface is the measure of its ability to emit radiant energy and, for the same temperature and wavelength, is equal to its absorptance (ratio of the radiant energy absorbed by a surface to the total radiant energy falling on it). The ratio of the energy reflected by the surface to that falling on it is called reflectance; for an opaque surface, reflectance is equal to one minus the emittance. This emittance varies with surface type and condition and radiation wavelength.

For reflective insulation used with heating, air-conditioning, and refrigeration applications, the emittance value for long-wavelength (infrared) radiation is important, and not the value for the shorter wavelengths of the visible spectrum. Visible brightness is not a true measure of the reflectance for thermal radiation, because the reflectance for light and for long-wavelength radiation is unrelated. Table 3, Chapter 22 lists typical reflectance and emittance values for reflective surfaces and building materials and the corresponding emittance factors for air spaces.

Chemical action, dust or oil accumulations, or the presence of condensation or frost can change a reflective surface enough to reduce its reflectance and increase its emittance. Chemical changes include oxidation, corrosion, or tarnishing caused by air, moisture, wet plaster, or the chemical treatment of wood spacing strips or other adjoining structural members. Surface emittance values should be obtained by tests, such as described in ASTM *Standard* C445. Low-emittance windows have significantly greater thermal resistance, for example.

CALCULATING OVERALL THERMAL RESISTANCES

Using the principles of heat flow presented in Chapter 3, calculating heat flow by the overall thermal resistance method is preferred.

The total resistance to heat flow through building constructions such as flat ceiling, floor, or wall (or curved surface if the curvature is small) is the numerical sum of the resistances (R-values) of all parts of the construction in series.

$$R = R_1 + R_2 + R_3 + R_4 + \ldots + R_n \quad (1)$$

where R_1, R_2, etc., are the individual resistances of the parts, and R is the resistance of the construction from inside surface to outside surface. However, in buildings, to obtain the overall resistance R_T the air film resistances R_i and R_0 must be added from Table 1, Chapter 22.

$$R_T = R_i + R + R_0 \quad (2)$$

The U-factor is the reciprocal of R_T.

$$U = 1/R_T \quad (3)$$

With the use of higher values of R_T, the corresponding values of U become very small. This is one reason why it is sometimes preferable to specify resistance rather than transmittance. Also, a whole number is more understandable to an insulation buyer than is a decimal or fraction.

An example of former calculations for a wall with air space construction, consisting of two homogeneous materials of conductivities k_1 and k_2 and thickness x_1 and x_2, respectively, separated by an air space of conductance C, is:

$$R_T = 1/h_i + x_i/k_1 + 1/C + x_2/k_2 + 1/h_o \quad (4)$$

Series and Parallel Heat Flow Paths

In many installations, components are arranged so that heat flows in parallel paths of different conductances. If no heat flows between lateral paths, heat flow in each path may be calculated using Equations (1) and (2). The average transmittance is then:

$$U_{av} = aU_a + bU_b + \ldots + nU_n \quad (5)$$

where $a, b, \ldots, n$ are respective fractions of a typical basic area composed of several different paths with transmittance U_a, $U_b, \ldots, U_n$.

If heat can flow laterally in any continuous layer so that transverse isothermal planes result, total average resistance $R_{T(av)}$ will be the sum of the resistance of the layers between such planes, each layer being calculated by the appropriate Equation (1) or modification of Equation (4), using the resistance values. This is a series combination of layers, of which one (or more) provides parallel paths.

The calculated heat flow, assuming parallel heat flow only, is usually considerably lower than that calculated with the assumption of combined series-parallel heat flow. The actual heat flow will be some value between the two calculated values. In the absence of test values for the combination, an intermediate value should be used; examination of the construction will usually reveal whether a value closer to the higher or lower calculated value should be used. Generally, if the construction contains any highly conductive layer in which lateral conduction is very high compared to heat flow through the wall, a value closer to the series parallel calculation should be used. If, however, there is no layer of high lateral conductance, a value closer to the parallel heat flow calculation should be used.

CALCULATING SURFACE TEMPERATURES

The temperature at any interface can be calculated, since the temperature drop through any component of the wall is proportional to its resistance. Thus, the temperature drop Δt through R_1 in Equation (1) is:

$$\Delta t_1 = R_1 (t_i - t_o)/R_T \quad (6)$$

where t_i and t_o are the indoor and outdoor temperatures, respectively. Hence, the temperature at the interface between R_1 and R_2 is:

$$\Delta t_{1-2} = t_i - t_1 \quad (7)$$

For types of building materials having nonuniform or irregular sections such as hollow clay tile or concrete blocks, it is necessary to use the R-value of the unit as manufactured.

If the resistances of materials in a wall are highly dependent on temperature, the mean temperature must be known to assign the correct value. In such cases, it is perhaps most convenient to use a trial and error procedure for the calculation of the total resistance R_T. First, the mean operating temperature for each layer is estimated, and R-values for the particular materials are selected. The total resistance R_T is then calculated as in Equation (4), and the temperature at each interface is calculated using Equations (6) and (7).

The mean temperature of each component (arithmetic mean of its surface temperatures) can then be used to obtain second generation R-values. This procedure can then be repeated until the R-values have been correctly selected for the resulting mean temperatures. Generally, this can be done in two or three trial calculations.

In many heating and cooling load calculations, it is necessary to determine the inside surface temperature or the temperature of

the surfaces within the structure. The resistances through any two paths of heat flow are proportional to the temperature drops through these paths and can be expressed as:

$$R_1/R_2 = (t_i - t_x) / (t_i - t_o) \quad (8)$$

where

R_1 = resistance from indoor air to any point in structure at which temperature is to be determined
R_2 = overall resistance of wall from indoor air to outdoor air
t_i = indoor air temperature
t_x = temperature to be determined
t_o = outdoor air temperature

HEAT FLOW CALCULATIONS

Equation (9) is used to calculate heat flow through flat surfaces; Equation (10) is used for cylindrical surfaces (Figure 5).

$$q_s = (t_{is} - t_{os})/R \quad (9)$$

and

$$q_s = \frac{t_{is} - t_{os}}{[r_s \ln(r_1/r_i)]/k_1 + [r_s \ln(r_s/r_1)]/k_2} \quad (10)$$

where

q_s = rate of heat transfer per unit area of outer surface of insulation
R = surface-to-surface thermal resistance from Equation (1)
k = thermal conductivity of insulation at calculated mean temperature
t_{is} = temperature of inner surface
t_{os} = temperature of outer surface
r_i = inner radius of insulation
r_1, r_2 = outer radius of intermediate layers of insulation
r_s = outer radius of insulation
ln = natural or Napernian logarithm

To calculate heat flow per unit area of pipe surface, use:

$$q_o = q_s(r_s/r_i) \quad (11)$$

where q_o = rate of heat flow per unit area of pipe surface, Btu/h·ft².

Heat flow per unit length of pipe is the preferred unit. For steady-state conditions, heat flow through each successive material is the same. However, the temperature drop through each material is proportional to its thermal resistance. The terms that appear in the denominators of Equations (9) and (10) represent the resistances to heat flow based on log mean thickness. The thermal resistances discussed for flat surfaces and a thermal resistance of a cylindrical insulation should not be confused where the surface areas involved are never equal.

Heat flow is inversely proportional to the sum of the resistances of the system. The various temperature drops in the system are proportional to the resistances.

The assumptions used for calculations of heat flow are usually as follows:

t_{is} = temperature at inner surface of insulation equal to temperature of fluid in pipe or container
t_o = still air ambient temperature
r_i = inner radius of insulation = outside radius of iron pipe
r_s = outer radius of insulation = $r_i + x$
x = equivalent thickness of insulation, based on log mean thickness versus flat insulation thickness equivalent in performance

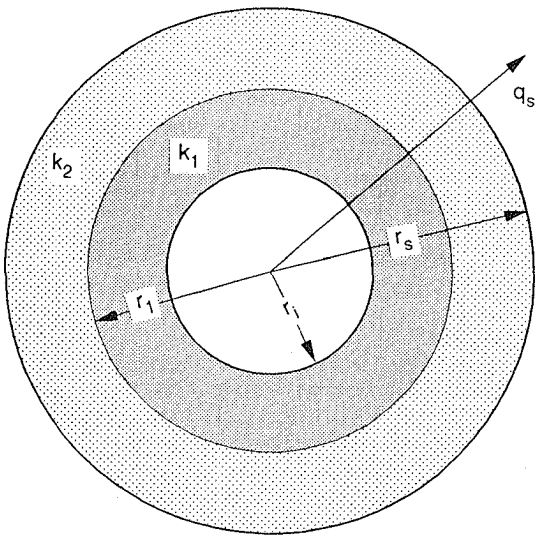

Fig. 5 Heat Flow through Cylindrical Surfaces

INSULATION THICKNESS

ECONOMIC THICKNESS: MECHANICAL SYSTEMS

Economics can be used (1) to select the optimum insulation thickness for a specific insulation or (2) to evaluate two or more insulation materials for least cost for a given thermal performance. In either function, economics determines the most cost-effective solution for insulating over a specific period (TIMA 1973, Federal Energy Administration 1976). This solution can be reached by different techniques, but only one solution exists for a given set of economic variables. This section presents the basic concepts used to determine economic insulation thickness for a single-insulation material system.

Greater than optimum insulation thickness may also require more capital investment for structure and piping. However, in some instances, limited energy availability may require more insulation than is normally justified by minimizing insulation and lost energy costs alone.

Determining the most profitable thickness of insulation is difficult. The economics of each plant, including cost of producing energy, cost of insulating, and potential for energy loss, indicate the preferred amount of insulation. Various types of equipment and piping also require different economic thicknesses. This analysis is further complicated because future energy cost and the life of the facility and insulation must also be considered. For every plant, these factors dictate different solutions to the economic analysis.

Economic Analysis

The cost of installed insulation increases with thickness. This incremental cost is for both labor and material. Insulation is often applied in multiple layers because materials are not manufactured in single layers of sufficient thickness and, in many cases, to compensate for expansion and contraction. Figure 6 shows installed costs for a multilayer application. The average slope of the curves increases with the number of layers because labor and material costs increase at a more rapid rate as thickness increases.

Since the optimal economic thickness is the lowest total cost of lost energy and installed insulation over the life of the insulation, these two costs must be compared in similar terms. Either the annual cost of the insulation must be compared to the average annual cost of lost energy, or the cost of the energy lost each year

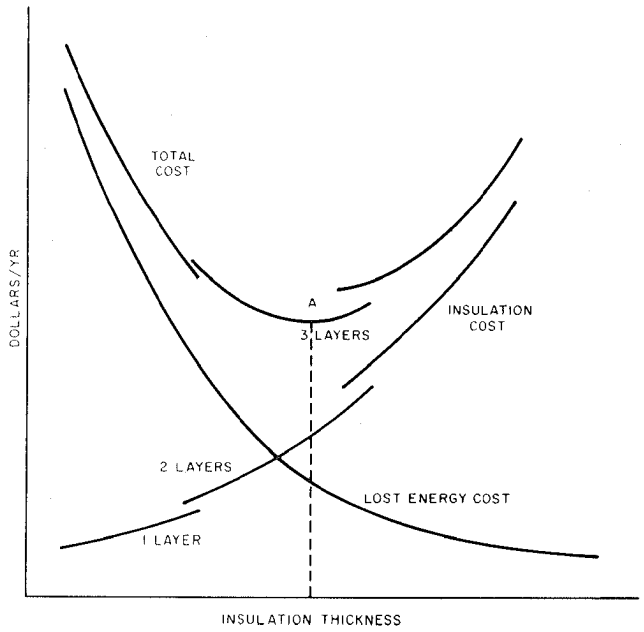

Fig. 6 Determination of Economic Thickness of Installed Insulation

must be expressed in present dollars and compared with the total cost of the insulation investment. The former method, annualizing the insulation cost and comparing this with the average annual cost of lost energy, is easier to compute.

Life cycle costing spreads the initial cost of the insulation over the number of years the insulation is expected to be in service. The life cycle selected affects the economic thickness of the insulation. Thinner insulation pays back on a short life cycle, while thicker insulation pays back over a longer cycle. An insulation system designed to pay for itself in energy savings in a short payback period that stays in service longer, does not produce the lowest total cost over the service period.

Annualized cost of the installed insulation must also be adjusted for the cost of money, which can be a discount rate including the desired rate of return on the insulation investment. Insulation system maintenance costs should also be included in the annual cost.

Since fuel cost is likely to change during the depreciation period (life of the facility or payback period), the average cost should be estimated and this value used rather than current cost.

Because it lowers energy demand, insulation reduces the size and capital costs of the heating and cooling equipment required for an installation. This capital cost may be annualized by considering the plant depreciation period, cost of money, annual energy output for the plant, and operational expenses.

Total Cost

Since the total annual cost represents the sum of the annual cost of insulation and the annual cost of lost energy, for each incremental increase in insulation thickness, the corresponding change in the total cost is given as:

$$m_t = m_c + m_s$$

where

m_t = incremental change in total annual costs
m_c = incremental change in cost of insulation
m_s = incremental change in cost of lost energy

Initially, as insulation is applied, the total cost decreases because the incremental energy savings is greater than the incremental cost of insulation. Additional insulation reduces this cost up to a thickness where the change in the total cost is equal to zero. At this point, $m_t = m_c + m_s = 0$, and no further reduction can be obtained. Beyond this thickness, the incremental insulation costs become greater than the additional energy savings derived by adding another increment of insulation.

Figure 6 shows curves of total annual costs of operation, insulation costs, and lost energy costs. Point A on the total cost curve corresponds to the economic insulation thickness, which, in this example, is in the double-layer range. Viewing the calculated economic thickness as a minimum thickness provides a hedge against unforeseen fuel price increases and conserves energy.

ECONOMIC THICKNESS: BUILDING ENVELOPES

In buildings such as residences and warehouses, the internal energy gains are insignificant compared with the heat losses and gains through the envelope. For these buildings, the heating and cooling requirements are roughly proportional to the difference between the indoor and outdoor temperature. For commercial, industrial, and institutional buildings, internal heat loads can be significant, and the heating and cooling requirements are not directly proportional to the indoor/outdoor temperature difference. In both types of buildings, solar heat can be an important factor and should be evaluated.

Dominant Heat Loss and Gain through Envelope

Thermal insulation is generally installed in building envelope components (*e.g.*, ceilings, walls, and floors) to reduce space heating (and, in some cases, cooling) costs on a long-term basis. Additional benefits may be increased occupant comfort, reduced requirements for heating and cooling system capacity and, perhaps, elimination of condensation on wall surfaces in cold climates. However, since these benefits are difficult to quantify and are likely to be negligible beyond a nominal level of thermal resistance, the following evaluation methods focus only on reductions in energy costs. The economically optimal insulation thickness (best measured in terms of thermal resistance) in an envelope component minimizes total life cycle space heating and cooling costs attributable to that component. Total life cycle costs are the sum of present-value heating and cooling costs over the useful lifetime of the insulation plus the installed cost of the insulation.

Generally, as the thermal resistance of the insulation is increased, space heating costs decrease, while insulation costs increase. As long as the additional reduction in present-value heating plus cooling costs (incremental savings) caused by an increase in insulation thickness exceeds the additional cost of that increased insulation thickness (incremental costs), total life cycle costs are reduced. But, as insulation thickness is increased, the incremental savings per unit change in resistance decreases while incremental insulation costs beyond the first resistance unit typically remain constant or increase. Since start-up costs are attributed to the first resistance unit, this may be the most expensive unit. Beyond a certain resistance level, incremental costs exceed incremental savings, so that such additions increase life cycle costs. At the point where incremental savings equal incremental costs, life cycle costs are minimized. However, if total insulation costs then exceed total insulation benefits, the optimal level of insulation for a given component is no insulation at all. This may occur if the start-up costs are extremely high, as when insulation is installed in a sealed cavity wall.

If the R-value of the insulation used is continuously variable (loose-fill insulation in attics), uniformly small increments of

insulation (R-1 . . .) can be used to determine appropriate optimal thicknesses; or calculus can determine an exact optimum. If the insulation materials used are available only in discreet levels of thermal resistance (R-12, R-18, R-27), the increment used in determining optimal thickness should be based on differences between those levels (R-12 over R-0, R-20 over R-12, R-27 over R-20). Where discrete increments of resistance are used, determining the resistance level for which incremental savings equal incremental costs may not be feasible. In such cases, the selection should be left to the judgment of the analyst based on the level of conservation desired.

If a building envelope component requires structural modifications to accommodate increased insulation thickness, its cost must be included in the installed cost of the additional insulation. Generally, such modifications should only be considered when they are less costly than the use of more efficient (*i.e.*, lower thermal conductivity), but more expensive, insulation materials than those ordinarily used.

Typically, the incremental energy savings and insulation costs differ for each building envelope component; therefore, the optimal insulation level differs for each component in the same building. Less efficient heating plants and higher costs of heating energy necessitate higher optimal insulation levels in each building envelope component. Conversely, more efficient heating equipment lowers the optimal insulation level. The effects of climate, cooling energy costs, and cooling equipment efficiency on optimal insulation levels are less clear and differ widely, depending on overall building design and operational profile.

Computation

Optimal insulation thickness is found by examining the incremental savings and costs of each additional level of insulation included in a building envelope component. The present-value, life cycle savings from each increment are calculated as follows:

$$\Delta LCS_{ij} = \Delta AHR_{ij}(P_h)^{n_h}(UPW_h)^* + \Delta ACR_{ij}{}^{n_c}(P_c)(UPW_c)^* \quad (12)$$

where

ΔLCS = present-value, life cycle savings in dollars from the i_{th} increment of insulation in the j_{th} component
$\Delta AHR, \Delta ACR$ = changes in annual heating and cooling requirements, respectively, of building due to the i_{th} increment of insulation in the j_{th} component (treating a reduction as positive)
n_h, n_c = seasonal conversion efficiencies (or coefficients of performance) of building's heating and cooling equipment, respectively
P_h, P_c = current costs per thermal unit for heating and cooling energy, respectively
UPW_h^* UPW_c^* = modified uniform present worth factors for heating and cooling energy types used, respectively

The terms ΔAHR_{ij}, ΔACR_{ij}, n_h, and n_c must be determined through thermal engineering analysis and require consideration of the overall building design, the climate, and the operational profile of the building. In some cases (floors), ΔACR_{ij} from additional insulation may be negative, *i.e.*, additional insulation may increase annual cooling requirements. Careful construction and insulation practices ensure that theoretical savings are actually realized.

The terms UPW_h^* and UPW_c^* relate present-value, life cycle savings to annual savings calculated at current energy costs. They are modified uniform present worth factors in the sense that they incorporate both a discount rate and a rate of energy price increase over the time horizon considered in the life cycle cost analysis. The UPW* is calculated as follows:

$$UPW^* = \frac{1+P}{D-P}\left[1 + \left(\frac{1+P}{1+D}\right)^L\right], \text{ in which } D \neq P \quad (13)$$

or $UPW^* = L$, in which $D = P$

where

P = annual rate of energy price increase
D = discount rate
L = useful life of insulation

Since different energy types may have different projected rates of price increase, UPW_h^* and UPW_c^* may differ when different energy types are used for heating and cooling. However, the same discount rate and lifetime should be used to determine the appropriate UPW* factors. Generally, longer lifetimes (30 years) rather than shorter lifetimes (10 years) approach true life cycle cost minimization more closely and avoid the high cost of retrofitting if energy prices increase.

Dominant Internal Heat Loads

In buildings with dominant internal loads, the energy requirements vary so widely that no generalizations can be made regarding insulation. This contrasts with envelope dominated structures, in which more insulation reduces energy consumption (Hart 1981).

In internal load dominated buildings with cooling, for cool climates having as many or more hours below room temperature than above, higher thermal resistance increases cooling energy consumption while reducing heating energy consumption. Therefore, the calculation of economically optimum resistance becomes quite complex and involves multiple measure or hourly methods described in Chapter 28. Spielvogel (1974), Burch and Hunt (1978), and Rudoy (1975) give more details.

Figure 7 shows the results of these calculations for a building in Columbus, Ohio, with 8.2 Btu/h·ft² of internal heat gains that operates 24 h per day (Spielvogel 1974). This solution is not the only one possible but brings forth problems faced by the designer.

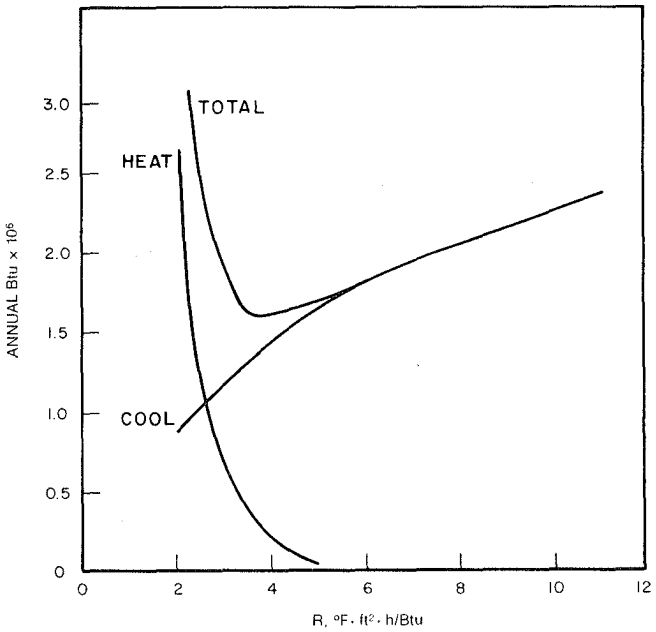

Fig. 7 Example of Optimal Thermal Resistance for Thermally Heavy Building
(Adapted from Spielvogel 1974)

As thermal resistance increases, U-value decreases, annual heating energy decreases, and annual cooling energy increases. The energy optimum exists at Point Y, where the total heating plus cooling energy is minimal. Because the cost of cooling energy differs from the cost of heating energy, the economic optimum will not be the same as the energy optimum.

These results occur in some localities because far more hours per year have outdoor temperatures of 50 to 75 °F than between 75 and 100 °F. At temperatures between 75 and 100 °F low, U-values result in less energy consumption for cooling; however, at temperatures between 50 and 75 °F, low U-values inhibit the flow of internal heat from the building, thereby creating higher cooling loads and higher energy requirements than those in buildings with higher U-values. What might be saved at outdoor temperatures over 75 °F can be more than spent in additional cooling energy at temperatures below 75 °F. Economizer cycles could offset these excess internal gains with ventilation air, however.

Where the hours of use or quantity of internal heat gains vary from room to room, the optimum thermal resistance also varies. For example, in a cold climate, a hotel kitchen requires little or no insulation, since the internal heat is sufficient to heat the space almost all year. In a meeting room adjacent to the kitchen, substantially more insulation will be justified. Thus, the economic thermal resistance of any envelope element, such as a roof, will not be the same throughout the entire building.

This type of analysis must include the level and duration of internal gains and the nature of the energy consumption of the heating and cooling systems. Most buildings need evaluation of walls, roofs, and floors on a room-by-room basis. Computer programs make these more complex analyses possible. Due to the wide diversity of building types, internal gains, system types, and operating conditions, no simple rules can establish U-values for minimum energy consumption.

Effectiveness of Added Insulation

The effectiveness of added insulation varies with many factors, including climate, original insulation level, preparation costs, and predicted life, based on payback calculations. Building codes generally balance life cycle costs between construction, financing, and energy expenditures. Figure 8 shows typical relationships between life cycle costs and energy consumption. Individual points on the curve represent different combinations of ceiling, wall, and floor insulation in R-values and glazing types (single, double, or triple). Since life cycle costs vary not only with construction and energy costs but also with climatic factors, the profiles of this curve vary according to locality. In Figure 8, the optimal condition is attained with R-30 attic insulation, R-18.7 wall insulation, and double glazing. However, the effectiveness of added insulation can be determined only by analyzing actual conditions.

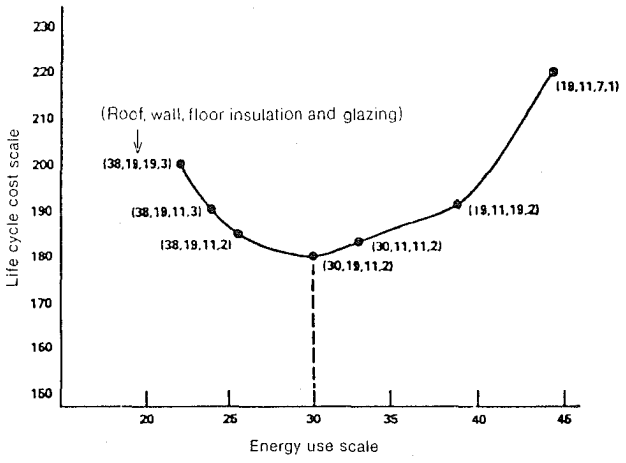

Fig. 8 Typical Life-cycle Cost Relationships

FUNDAMENTALS OF MOISTURE IN BUILDINGS

PROPERTIES OF WATER VAPOR IN AIR

Water vapor is a gas occupying the same space as the other gases that collectively constitute air and, like them, acts independently. It can migrate with or against airflow and follows its own physical laws of migration. The atmosphere is an air and vapor mixture that must be evaluated for conditions anticipated in building operation. For any given temperature and degree of saturation, water vapor in the air exerts a specific vapor pressure; it diffuses or migrates from points of higher vapor pressure toward points of lower vapor pressure, whether in air or within materials.

Effect of Temperature Change

Changes in mixtures of air and water vapor properties with heating and cooling can be followed using a psychrometric chart, shown in outline in Figure 9. A common indoor condition, 70 °F and 40% rh, is found at point A. Cooling from condition A on the chart to point B is accompanied by increasing relative humidity. At B (45 °F dew point), the relative humidity becomes 100%, and the air/vapor mixture is saturated. On further cooling to 35 °F, the original amount of water vapor is reduced by condensation to condition C, from 0.00633 lb/lb dry air to 0.00427 lb/lb dry air. ABC is the typical process that an air/vapor mixture experiences when it contacts a cool window surface. Cooling from B to C causes visible condensation on the glass. If point C is below 32 °F, the condensate would be frost. For either dew or frost to form, heat must be removed from the water vapor. All conditions on DE are at lower vapor pressure than all points on AB, so moisture will flow from the higher to the lower vapor pressure without necessarily reaching dew points. A common winter process is that shown by DE, where saturated air at 19 °F is heated to 70 °F with a resulting large decrease in relative humidity. This change explains, in part, the greatly reduced relative humidities experienced in buildings in cold weather, when cold outdoor air with high relative humidity enters and is heated.

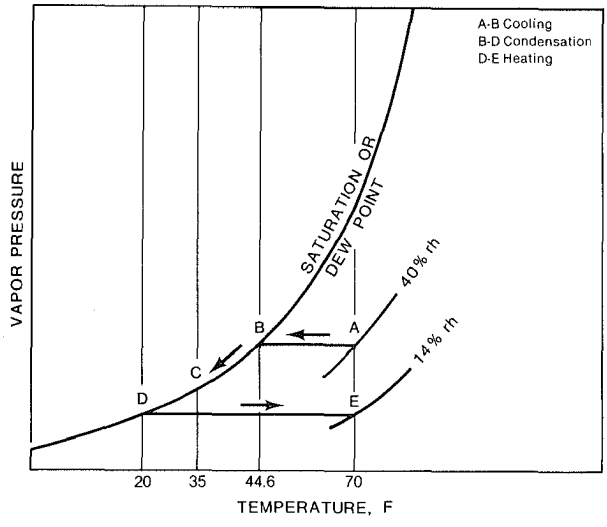

Fig. 9 Typical Cooling and Heating Processes in Buildings

At certain conditions (ice point for ice and water and triple point for ice, water, and vapor), the different physical states can exist together.

Effect of Surface Temperature at or Below Dew Point

The vapor pressure at the condensing surface lowers when the temperature drops below the dew point or frost point, at a window surface, for example. This vapor pressure gradient and convective action in the room moves water vapor continuously to the window surface to be condensed, as long as the room's concentration of water vapor is maintained.

WATER IN BUILDING MATERIALS

Many common building materials have a large number of interstices that may or may not be interconnected. Collectively, they present a large internal surface area that has an affinity for water molecules. Molecular forces of attraction hold water molecules to the surface but decrease very rapidly as the distance of molecular proportions increases. The film thickness and the amount of water held in equilibrium with the surrounding atmosphere is roughly proportional to relative humidity. Surface films of water molecules at low humidities may be only one molecule thick; at moderate humidities, polymolecular films may be established; and at humidities very close to 100%, the films become so thick that small pores can be filled and larger interstices can be partially filled. At saturation conditions, all voids in the material may be filled.

Some materials such as silica gel, alumina, and most natural fibrous materials present large effective internal surfaces to the water molecules, so the amount of water held on the effective surface in these materials can be relatively large, even at moderate humidities. These materials are said to be hygroscopic. Other materials, such as most metals, not penetrated by the water molecules present relatively small internal surfaces and may take only minute quantities of water, except when wetted directly by liquid.

Chapter 19 describes hygroscopic substances with a great affinity for water and their use as dehumidifying agents. Table 2, Chapter 12 of the 1991 ASHRAE *Handbook—HVAC Applications* gives data on the moisture content of various common materials in equilibrium with the atmosphere at various relative humidities.

Wood and other hygroscopic materials change dimensions with variations in moisture content (MC). The MC of wood varies with the relative humidity and temperature of its ambient air. The point at which a material neither gains moisture from the air nor releases moisture to the air is the *equilibrium moisture content* (EMC). The MC at which cell walls are saturated but no free water exists in cell cavities is the *fiber saturation point*. It represents the upper limit for moisture gain from the air as water vapor. It is also the upper limit of swelling; while more water can be absorbed in cell cavities, swelling is not increased. Wood MC is expressed as a percentage of its oven dry weight. The average fiber saturation point for most species is about 30%. The average EMC at 68°F and 45% rh (heating season indoor conditions) is about 8.5%. At 75°F and 70% rh (summer conditions), the EMC is about 13%.

The resulting dimensional changes in wood are proportional to change in moisture content, but vary with species and direction of grain. For white oak, as representative of interior trim material, 4.5% MC variation causes 2.5% volumetric shrinkage or swelling. Longitudinal dimensional change in straight-grained wood is insignificant, but it increases with crossgrain and other irregularities. Accordingly, residential wood trusses with top and bottom chords exposed to different temperature and moisture regimes can show measurable seasonal vertical movements (Plewes 1976).

Most plant and animal fibers undergo dimensional changes similar to those noted in wood. Typical values for wood can be found in Table 2; the *Wood Handbook* (FPL 1974) gives more detailed information. Related changes in other materials are not as well documented. However, different expansion rates caused by temperature and moisture changes in different materials used in composite constructions should be considered (Baker 1964, Building Research Station 1979).

Degradation of Materials

Materials exposed to excess moisture may experience reversible performance degradation or irreversible deterioration caused by (1) physical changes (such as masonry spalling on freezing), (2) chemical (steel rusting), or (3) biological (wood decaying) processes. The presence of water may be attributable to condensation, roof and window leaks, capillary flow from the ground, or any combination of these sources.

Wood construction is tolerant of heating season moisture accumulations. If the wetted wood can dry out before the onset of decay-conducive temperatures, moisture levels do not cause glue joints or paint films to fail, and moisture buildup does not occur in assemblies that are difficult to protect.

Decay is a warm weather phenomenon, most active at temperatures between 50 and 100°F and essentially inactive when the temperature drops below 35°F. The required wood MC to sustain decay has been estimated at 24 to 31%. Once established, decay fungi produce 0.55 lb of water for every pound of cellulose decomposed. For a sufficient safety margin, the MC should remain at 20% or less (De Groot 1976).

Molds can grow on surfaces of air dry wood (below 20% MC) at relative humidities above 85%. Condensation on wood surfaces cooled by heat radiation to the sky at night is an important moisture source for these fungi (De Groot 1976).

Table 2 Shrinkage Values of Wood, from Green to Oven Dry Moisture Content

Wood Species	Radial %	Tangential %	Volumetric %
Hardwoods			
Birch			
Yellow	7.3	9.5	16.8
Oak			
Northern Red	4.0	8.6	13.7
Southern Red	4.7	11.3	16.1
White	5.6	10.5	16.3
Softwoods			
Cedar			
Northern White	2.2	4.9	7.2
Western Red Cedar	2.4	5.0	6.8
Douglas Fir			
Coast	4.8	7.6	12.4
Fir			
White	3.3	7.0	9.8
Hemlock			
Western	4.2	7.8	12.4
Pine			
Eastern White	2.1	6.1	8.2
Longleaf	5.1	7.5	12.2
Ponderosa	3.9	6.2	9.7
Redwood			
Young Growth	2.2	4.9	7.0
Imported wood			
Lauan	3.8	8.0	—

Note: Value expressed as a percentage of the green dimension (FPL 1974).

Although condensation may have occurred in wall cavities during winter, the moisture content of wood framing members generally falls below the 25 to 30% level in spring because of normal drying, unless water has leaked in around windows and joints in the exterior surface or from an ice dam on the roof. Typical moisture levels and temperatures in roof cavities result in a more decay-conducive environment. Consequently, the incidence of decay and delamination in roof framing or sheathing is higher than that in wall construction, unless the wall is filled with material that dries slowly.

Effect of Moisture on Heat Flow

Pedersen (1990), Pedersen *et al.* (1991), Kumaran (1991), Hedlin (1983), Langlais *et al.* (1983), Thomas *et al.* (1983), Bomberg *et al.* (1978, 1991), Tobiasson *et al.* (1979), and Paljak (1973) show that the effect of moisture on heat flow depends on the nature of insulation, the moisture content, and the temperature of the insulation. The moisture may contribute to heat flow in both sensible and latent forms. The first occurs under all temperature conditions. However, the second requires evaporation and condensation and is most active when daily reversals in temperature across the insulation drive moisture back and forth. For example, in a flat roof, during cool nighttime temperatures, moisture migrates upward and condenses in the upper part of the insulation. In the heat of the following day, the temperature is reversed and the moisture is driven downward, transporting heat in the process. The movement depends on the porosity of the insulation. In closed-cell insulations, migration is slow, whereas in porous insulations, it may make a large contribution to energy transfer.

In cold weather, the temperature reversals cease and the driving forces exist only in one direction, *i.e.*, upward in flat roof insulation. In this situation, moisture accumulates in the cold region of the insulation as liquid or frost. Transfer by vapor movement substantially ceases. Epstein *et al.* (1977) and Larsson *et al.* (1977) showed a nearly linear increase in energy transfer of about 3 to 5% for each percent increase in moisture content, by volume. For example, insulation with 5% moisture content by volume would have 15 to 25% greater energy transfer than dry insulation. Other field studies by Dechow *et al.* (1978) and Ovstaas *et al.* (1983) have shown similar results for insulations installed in below-earth applications, as highways and foundation walls.

In porous insulations, when temperature reversals occur, the effect of moisture follows a different pattern. Hedlin (1988) and Shuman (1980) showed the rate of energy transfer increased sharply as the moisture content increased to about 1%, by volume. The rate of increase diminished rapidly with further increase above that moisture content. The effect was strong; the rate of energy transfer for insulation with 1% moisture content was roughly twice that for dry insulation.

Moisture Effect on Heat Storage

Moisture also affects the thermal storage capacity of hygroscopic building materials considered composites of a given substance and water. At 10% MC, nearly 30% of the heat storage capacity of wood is in the water held in the cell walls. Since the specific heat of wood is a function of its temperature and moisture content (but almost independent of density and species), heat storage calculations must include an estimate of the equilibrium in-service moisture content of wood-building components.

In studies of hourly temperature and moisture content variations in insulated wood frame wall cavities, Duff (1971) showed measurable levels of daily moisture migration across the cavity. With nearly impermeable interior and exterior surfaces, such moisture migration could be viewed as a heat storage rather than a heat flow mechanism. However, the effects of moisture migration within the wall construction on solar heat gains through opaque wall surfaces remain unquantified.

WATER VAPOR MIGRATION

As a constituent part of the atmosphere, water vapor always migrates with airflow. As an independent gas, it also migrates by diffusion through air and materials according to its own pressure differentials. Moisture diffusion in free air is rapid, resulting in minimal vapor pressure differentials between connected spaces and rapid flow to condensing surfaces, such as cold glass or dehumidifier coils. As a result, vapor pressure differentials in buildings and across the building envelope usually are not as strong a driving force as air convection. Conversely, in industrial applications such as cold storage or built-in refrigerators, the primary driving force is diffusion. Therefore, the control of diffusion becomes more important with improved convection and air leakage control in buildings.

Basic Diffusion Equation

The equation used in calculating water vapor diffusion through materials is based on a form of Fick's law:

$$w = -\mu\,(dp/dx) \tag{14}$$

where

w = mass of vapor diffusing through unit area in unit time
p = vapor pressure
x = distance along flow path

Hence,

dp/dx = vapor pressure gradient
μ = permeability

Fick's law closely parallels Fourier's equation for heat flow. The actual diffusion of vapor through a material is complex; the coefficient μ is not simple, but is a function of relative humidity and temperature and may vary along the flow path through the material (Chang and Hutcheon 1956).

However, if μ is taken as the average permeability coefficient applicable to varying conditions along the flow path of length l and is assumed to be independent of vapor pressure and temperatures, Equation (14) can be rewritten as:

$$M_v = \mu A \Theta (\Delta p / l) \tag{15}$$

where

M_v = total mass of vapor transmitted
A = area of cross section of flow path, ft^2
Θ = time during which transmission occurred, h
Δp = difference of vapor pressure between ends of flow path, in. Hg
l = length of flow path (or thickness of specimen), in.
μ = average permeability, gr/h · ft^2 · (in. Hg) (see Table 9, Chapter 22)

Whenever a material of a stated or implied thickness is other than the unit thickness to which μ refers, the permeance coefficient M, which equals μ/l, should be used. The designation M for the symbol of permeance is a convenient substitute for the unit gr/h · ft^2 · in. Hg. The corresponding flow equation is:

$$M_v = M A \Theta \Delta p \tag{16}$$

where M is the permeance coefficient, gr/h · ft^2 · in. Hg. See Table 9, Chapter 22 for typical permeance and permeability values.

Resistance to vapor flow provided by a sheet or board is the reciprocal of the permeance:

$RV = 1/\mu$ = resistance to water vapor flow, in. Hg · ft^2 · h/gr

The designation *rep* is a convenient substitute for the unit resistance of one in Hg · ft^2 · h/gr.

The overall vapor resistance of an assembly (such as a wall) of materials in series is the sum of the resistances of its component parts:

$$G_t = G_1 + G_2 + G_3 + \ldots + G_n$$

The flow equation using resistance is:

$$M_v = A\Theta\Delta p/G \quad (17)$$

This simple vapor flow theory, as in the corresponding simple heat flow theory, assumes conditions of unidirectional, steady-state flow. Useful calculations can be made for an assembly or subassembly where the inflow and outflow of vapor are equal (a condition at which no condensation occurs) if a resistance applicable to actual conditions can be assigned to each component. Overall resistances, vapor pressures, and vapor flow can be calculated; in conjunction with thermal calculations, relative humidities can be determined and the imminence of condensation predicted. (See Example 1, Figure 10. Also, see Chapter 19 for use of vapor flow calculations.)

Example 1. A wood frame wall is exposed to indoor conditions of 70°F and 50% rh with a vapor pressure of 0.37 in. Hg and outdoor conditions of 0°F and 80% rh with a vapor pressure of 0.03 in. Hg. The wall is painted plaster on gypsum lath on the inside over 2 by 4 studs, with mineral wool fill between studs, 1 in. wood exterior sheathing, paper, and pine lap siding. Check for possible condensation.

To simplify the example, consider the paint, plaster, and lath as a single element, with a vapor resistance $G = 1$ rep and a thermal resistance $R = 0.42$. The exterior sheathing, paper, siding, and paint are another single element for which the vapor resistance is 0.5 rep and $R = 2$. From Table 9, Chapter 22, the value for the resistivity (to vapor flow) or resistance per unit of thickness of mineral wool fill is 0.0086 rep/in. For mineral wool, the thermal resistivity is 3.7°F·ft²·h/(Btu·in).

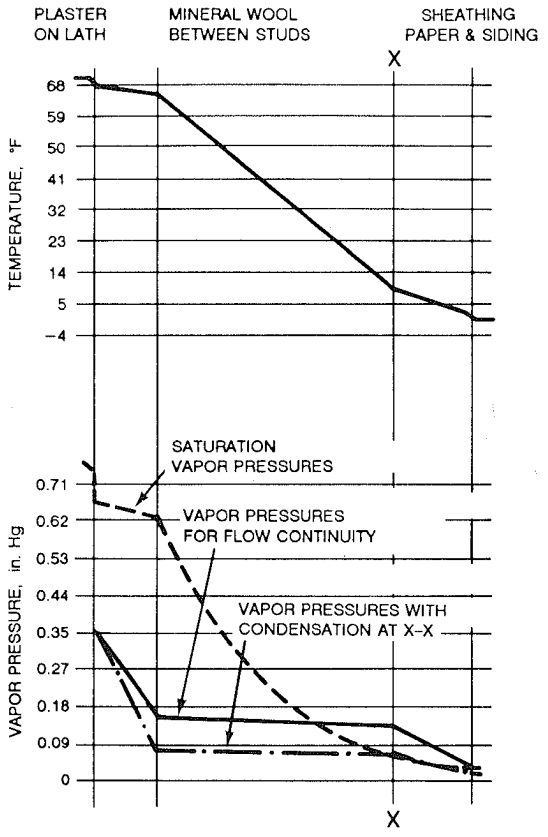

Fig. 10 Temperatures and Vapor Pressures in the Insulated Frame Wall of Example 1

Solution: In this insulated wall, with moderate warm-side relative humidities, condensation is unlikely to occur until the sheathing is reached. To check for condensation on the warm side of the exterior sheathing (designated as plane X-X in Figure 10 for convenient reference), proceed as follows:

According to the method described earlier, calculate the temperature at plane X-X. This is 9°F. The saturation vapor pressure at this temperature is 0.06 in. Hg. If condensation is imminent or occurs at X-X, the vapor pressure at that point will be 0.06 in. Hg. Calculate the resistance for the portion of the wall from the warm side to X-X, and the vapor flow rate to X-X:

Resistance of wall to X-X = 1 + (0.0086 × 3.625) = 1.03 rep

Vapor pressure drop to X-X = 0.37 − 0.06 = 0.31 in. Hg

Vapor flow to X-X = 0.31/1.03 = 0.30 gr/h·ft²

Calculate the vapor flow rate from X-X to outdoors:

Resistance of wall from X-X to outdoors = 0.5 rep

Vapor pressure drop from X-X to outdoors = 0.06 − 0.03 = 0.03 in. Hg

Vapor flow rate to outdoors = 0.03/0.5 = 0.06 gr/h·ft²

Interpretation of calculations. Continuity of vapor flow is impossible in this example. At the highest vapor pressure permitted by the temperature at X-X in Figure 10, the calculations indicate a greater flow to plane X-X than from plane X-X to outdoors. Condensation is indicated at a rate of 0.30 − 0.06 = 0.24 gr/h·ft².

The designer must decide whether this condensation rate is serious, since it might readily be absorbed by the sheathing without excessive wetting. When the temperature at X-X is below freezing, as in this case, condensation will be frost, which may accumulate until released over a short period with a rise in outdoor temperature.

Condensation may be reduced or avoided if the resistance of the warm side of the wall can be increased so that the flow to X-X is limited to 0.06 gr/h·ft². The resistance required for this is (0.37 − 0.06)/0.06 = 5.2 rep or more. A more resistant paint film on the plaster to increase the paint-plaster-lath resistance to 5.2 rep would also accomplish this.

Determining Critical Temperature Location

If the critical plane for condensation is unknown or if a more informative, graphical representation of the situation throughout the wall is required, temperatures and vapor pressures can be calculated and plotted, as in Figure 10. For continuity of flow, the vapor pressures throughout the wall are calculated in a manner similar to the temperatures; the external vapor pressures are given, and the vapor pressure drops across each element are taken in proportion to resistance to vapor flow.

The curve for saturation vapor pressures at the various temperatures throughout the wall (Figure 10) falls below the curve for vapor pressures with continuity of flow toward the outer portions of the wall. Thus, with the given temperatures and vapor pressures, continuity of flow is not possible, and condensation occurs. Condensation on the sheathing is a definite possibility, and the new vapor pressure curve can be constructed for this condition, as shown. This new curve does not rise above the saturation vapor pressure curve, thereby confirming that the critical plane for condensation was correctly assumed.

With the vapor pressures established, the relative humidities can be found by referring to the saturation vapor pressures. The permeances assigned to the various elements can then be reexamined in the light of the indicated temperatures and relative humidities, and the analysis repeated, if necessary, using more appropriate permeance values. In a more detailed analysis, individual values might be assigned to the elements forming the outer portion of the wall, dealt with here as a composite, homogeneous element.

WATER VAPOR RETARDERS AND AIR BARRIERS

Water vapor retarders and air barriers combine to control the movement of moisture and air. While their functions are different, a single component may serve both functions. The designer should assess the needs for moisture and air movement in the building envelope and provide a system that combines the required vapor retarder and air barrier properties.

VAPOR RETARDER FUNCTIONS AND PROPERTIES

A vapor retarder is a component that retards vapor movement but does not totally prevent its transmission. In building structures, vapor retarders may allow moisture to flow through the system and exit to the outside. However, all cold surfaces that are impervious to moisture flow must be insulated with a system that has a vapor barrier jacket, or with insulation that is impervious to moisture vapor. For example, for pipes carrying cold fluids on a continuous basis, there is no egress; any moisture moving into the system will remain there and eventually result in an unacceptable accumulation.

In HVAC applications, vapor retarders are applied to thermal insulation on tanks, cold pipes, ducts, refrigerated enclosures, and buildings. They retard water vapor diffusion. If conditions are conducive to condensation, water vapor retarders help (1) keep the insulation dry and reduce heat load requirements for the cooling system; (2) prevent structural damage by rot, corrosion, or the expansion of freezing water; and (3) reduce paint problems on exterior wall construction (ASTM 1975).

In addition to vapor permeance, the following properties of vapor retarders are important, depending on the application:

- mechanical strength in tension, shear, impact, and flexure
- adhesion
- elasticity
- thermal stability
- fire and flammability resistance
- inertness to other deteriorating elements
- ease of fabrication, application, and joint sealing

Any vapor retarder's effectiveness depends on its vapor permeance, installation, and location within the insulated section. The vapor retarder is usually located at or near the surface exposed to the higher water vapor pressure. For residences with heating systems, this is usually the winter-warm side of the insulation.

Under conditions of reversible water vapor flow that can occur during temperature cycling of industrial insulations or of special-purpose buildings, the selection and location of water vapor retarders require special study and treatment (Stachelek 1955).

In the construction industry, the common rating of a vapor retarder for use in domestic construction is 1 perm or 1 rep. This stems from the definition of the perm given at the beginning of this chapter. Ratings below this value may be specified by the designer.

Vapor retarder material is usually a thin sheet or coating. However, a construction of several materials, some perhaps of substantial thickness, could also constitute a vapor retarder system.

Korsgaard and Pedersen (1989) describe a vapor retarder composed of a synthetic fabric sandwiched between sheets of plastic film. The fabric wicks free water from the building envelope, while the film retards vapor flow into it.

Water vapor permeances and permeabilities of some vapor retarders and other building materials are presented in Table 9, Chapter 22.

A vapor barrier material is usually sheet metal with soldered seams; heavy foil with wide, sealed overlaps; plastic pipe; or other zero-permeance systems.

AIR BARRIER FUNCTIONS AND PROPERTIES

Wind and stack effects in buildings cause outdoor and indoor air exchange. This results in the exchange of heat and the transfer of moisture. Exfiltrating air carries moisture that may condense in the envelope of the building, causing a variety of moisture problems (Chapter 21). In summer, infiltration of air adds to the sensible cooling load. Further, in warm humid climates, infiltrating air may bring moisture with it and add to the latent cooling load.

The exchange of air may produce beneficial ventilation; however, the balance problems caused by this exchange of air outweigh its usefulness, and buildings should be designed and built to control air exchange through the envelope.

Condensation of moisture in building envelopes can cause serious problems. It may be transported there by diffusion and by exfiltrating air. Exfiltrating air in buildings normally transports far more moisture than does diffusion, as illustrated in the following example: Assume a temperature of 70°F and a relative humidity of 35% (vapor pressure 0.259 in. Hg) on the warm side of a 1 perm vapor retarder 1000 ft² in area. On its cold side, the temperature and relative humidity are assumed to be 0°F and 100% (vapor pressure 0.0377 in. Hg), respectively. The rate of transport through the vapor retarder by diffusion will be:

$$W = (0.259 - 0.0377)\ 1000 \times 1 = 221 \text{ gr/h or } 0.032 \text{ lb/h}$$

Assume that the same vapor retarder has a hole of area A equal to 10 in², *i.e.*, 0.069 ft², in it. This equals 1 in²/100 ft² and corresponds to tight construction. Further, at 70°F, the density of air ρ is 0.075 lb/ft³ and the specific volume of evaporation is 867 ft³/lb. Assume that the pressure drop $p_1 - p_2$ across the hole is 0.02 in. of water. In that case, the volume rate of airflow through an orifice (as discussed in Chapter 32) will be:

$$Q = 60 \times 1097 \times 0.62\, A\, [(p_1 - p_2)/\rho]^{0.5} = 1460 \text{ ft}^3/\text{h}$$

Associated with this air will be $1460 \times 0.35/867 = 0.59$ lb/h of moisture.

Thus, 0.59/0.032 are approximately 18.5 times as much moisture would move through the 10 in² hole by airflow as would move through the 1000 ft² of vapor retarder by diffusion.

Note: The pressure drop across the vapor retarder was assumed to be 0.02 in. of water. This is only an example—pressure drop across the vapor retarder varies with wind and stack forces and with the airtightness of other components of the envelopes.

Air permeates through many building materials. Thus, low air permeability is a requirement for an air barrier; for example, 3.28×10^{-4} ft³/s per square foot under a pressure difference of 1.57 lb/ft².

Overall control of moisture requires both a vapor retarder and an effective air barrier. A vapor retarder also restricts airflow; large amounts of air will pass through it only where it is breached. Thus, a vapor retarder may also be an air barrier, *i.e.*, an air/vapor retarder. In the past, many designs were based on this fact; measures were taken to ensure that the vapor retarder was continuous in order to control airflow through it. This remains a valid approach. Some recent designs treat air barriers and vapor retarders as separate entities, but an "air barrier" should not be placed in a location where it can cause moisture to condense because of its "vapor retarder" properties. For example, an air barrier placed on the cold side of a building envelope may cause condensation, particularly if the vapor retarder is ineffective and the air barrier is impermeable to moisture.

The effectiveness of an air barrier can be greatly reduced if openings, even small ones, exist in it. Such openings can be caused by poor workmanship during application, poorly sealed joints and edges, insufficient coating thickness, improper caulking and flashing, uncompensated thermal expansion, mechanical forces, aging, and other forms of degradation. Common faults or leaks occur at electrical boxes, plumbing penetrations, telephone and television wiring, and other unsealed openings in the structure. In flat roofing, mechanical fasteners are sometimes used to adhere the system to the deck. These often penetrate the air barrier, and the resulting hole may allow air and moisture leakage into the roof.

Because it resists airflow, an air barrier must withstand pressures exerted by chimney (stack) and wind effects, or both, during construction and over the life of the building. The magnitude of the pressure varies depending on the type of building and the sequence of construction. At one extreme, single-family dwellings may be built with the exterior cladding partly or entirely installed and insulation in place before the air barrier is added. In addition, chimney effects in such buildings are small even in cold weather, so stresses on the air barrier during construction are small.

At the other extreme, in tall buildings, wind and chimney-effect forces are much greater than they are on single-family or other low buildings. Thus a fragile, unprotected sheet material used as an air barrier (or vapor retarder) on a tall building will probably be torn by the wind before construction is completed.

In summary, an air barrier must:

- meet air permeability requirements
- be continuous
  - tight joints in the air barrier must be constructible
  - it must accommodate dimensional changes due to temperature or shrinkage without damage to joints or the air barrier material
  - effective bonds in the air barrier must be made at intersections, *e.g.*, wall/roof
- be strong enough to support the stresses applied to it
  - it must not be ruptured or excessively deformed by air pressures due to wind and stack effects
  - where an adhesive is used to complete a joint, it must be designed to withstand forces that might gradually peel it away

Note: A small penetration across an air barrier system may seriously affect its performance. It concentrates the air/vapor flow in such a way that large local deposits of water/ice are possible. Calculations using permeance values are useless when holes are involved.

Classification of Vapor Retarders

Water vapor retarders are classified as rigid, flexible, or coating materials. Rigid retarders include reinforced plastics, aluminum, and stainless steel. These retarders usually are mechanically fastened in place and are vapor-sealed at the joints.

Flexible retarders include metal foils, laminated foil and treated papers, coated felts and papers, and plastic films or sheets. Such retarders are supplied in roll form or as an integral part of a building material (*e.g.*, insulation). Accessory materials are required for sealing joints.

Coating retarders may be semifluid or mastic; paint (arbitrarily called surface coatings); or hot melt, including thermofusible sheet materials. Their basic composition may be asphaltic, resinous, or polymeric, with or without pigments and solvents, as required to meet design conditions. They can be applied by spray, brush, trowel, roller, dip or mop, or in sheet form, depending on the type of coating and surface to which it is applied. Potentially, each of these materials is an air barrier; however, to meet air barrier specifications, it must satisfy the requirements for strength, continuity, and so forth.

Designers have many options. For example, the conditions for control of airflow and moisture movement might be achieved using an interior finish, such as drywall, to provide strength and stiffness, along with a low-permeability coating, such as a vapor retarder paint, to provide the required low level of permeance. In that case, edge sealing would be needed to establish continuity with adjacent air barrier/vapor retarder components.

Other designs may use more than one component. However, (1) any component that qualifies as a vapor retarder also impedes airflow, and is thus subject to pressure differences that it must resist, and (2) any component that impedes airflow also retards vapor movement and delays the exit of moisture to the outdoors. Even if it has a high permeance to water vapor, the vapor retarder may promote condensation or frost formation. The rate of diffusion of water vapor across a building component depends on the product of its permeance and the vapor pressure difference. If the air barrier is situated in a cold part of the envelope, the vapor pressure difference across it may be so small that transmission rates through it are too low to remove vapor supplied from interior sources. This is illustrated in Example 1.

Additional information regarding the control of moisture and airflow through the use of vapor retarders and air barriers may be found in Chapters 22 and 23 and in CSC TEK-AID (1990).

Vapor Diffusion through Vapor Retarders

Foil and foil laminate vapor retarders are used extensively in construction. Foil damages readily when handled; pinholes are easy to spot by holding the foil over a light table in a darkened room, although this is impractical as a field test.

An example of the effect of holes in foil is illustrated by the following tabulation for a typical 0.7-mil (0.0007 in.) foil scrim-kraft laminate.

Condition	Perms
As received	0.02
35 pinholes per square foot	0.04
A few holes larger than pinholes	0.08 to 0.16

A laminate of 0.33-mil thick foil/polyethylene, adhesive/kraft paper has 75% lower permeance (on the average) than a similar laminate made with a latex adhesive, because the polyethylene tends to seal the small holes and cracks in the aluminum foil. Foil 1-mil thick has better corrosion resistance than 0.70-mil foil, and better resistance to handling damage. The improvement is greater than predicted from the 0.30-mil extra thickness.

In any application where high humidity or condensation might be expected, flame resistant foil-kraft laminates must be selected carefully. Some laminates contain a salt flame retardant in the paper that can be highly corrosive to the foil. Many examples have been found where the vapor retarder was corroded to the point of uselessness within 6 months' service.

Most vapor retarders cannot be considered truly homogeneous materials. Doubling the thickness often more than halves the permeance. For example, a vapor retarder mastic has been tested at a dry coating mass of 0.22 lb/ft^2 with a permeance of 1.7 perm—not a good vapor retarder. However, at 0.44 lb/ft^2, the permeance was 0.06 perm, which is an excellent vapor retarder if installed properly. Most vapor retarder coatings have a minimum thickness at which acceptable permeability is attained.

Joints must also be considered. A typical field-applied system, which has a permeance of 0.01 perm in the laboratory, may have an effective overall permeance of 0.05 perm, even with carefully sealed joints. The vapor retarder is the most important component of any low-temperature insulation system. Insulation systems for low-temperature piping and tanks must have a vapor retarder with permeance close to zero, because the vapor pressure difference always drives moisture toward the metal surface.

PERMEANCE AND LABORATORY TESTING

Wet-Cup versus Dry-Cup Methods

The permeance of a specimen is found by sealing it over the top of a cup containing desiccant or water. It is then placed in a controlled atmosphere and weighed periodically. The steady rate of weight gain or loss is normally the water vapor diffusion. When the cup contains a desiccant, the procedure is called the dry-cup method; when it contains water, the wet-cup method (ASTM E-96). Usually, the surrounding atmosphere is held at 50% rh, which provides substantially the same vapor pressure difference in either method. However, the two methods produce very different results, with the wet-cup producing the higher values. The relationship between these values is best understood by referring to Figure 11 at one temperature (isothermal conditions) for a material such as wood.

The vapor permeability varies moderately at low humidities, but it grows at an increasing rate at higher humidities. The dry-cup test of this material, with 0% rh on one side and 50% on the other, exhibits a variation in spot permeability throughout its thickness because of the variation in relative humidity. The average permeability μ, by definition, from Equation (14) is:

$$\int_{p_1}^{p_2} \mu dp/(p_1 - p_2) \tag{18}$$

Since at a fixed temperature a linear relationship vapor pressure and relative humidity follow a linear relationship, this expression corresponds to the mean height of the area under the spot permeability curve, between the appropriate relative humidity limits. The average permeability found for dry-cup conditions should, therefore, have the value μ_1. Similarly, for the wet-cup test between 50 and 100% rh, the value should be μ_2. These values for wood and wood fiber materials are commonly in a ratio of 1:3 or higher (Table 9, Chapter 22).

Other Limits

Average permeability μ for other relative humidities at a particular temperature is the mean height of the area under the curve of spot permeability for the material at that temperature, between the appropriate limits of relative humidity. Only average permeabilities (or permeances) are directly measurable in practical tests. But, if several average permeabilities at different relative humidities are known and can be plotted as in Figure 11, a spot permeability curve can be plotted by trial and error. The average height of this curve between the appropriate limits for each test must equal the value found in each test. Since each temperature requires separate tests, a large number of permeance cup tests are needed to cover a range of both temperature and humidity conditions.

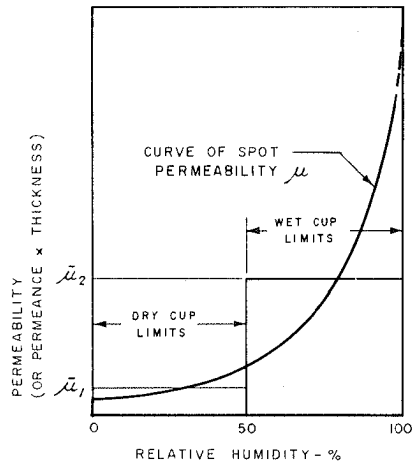

Fig. 11 Relation between Dry- and Wet-Cup Tests and the Spot Permeability for a Material such as Wood

Temperature Effect

The permeability constants of the least permeable membranes may be highly sensitive to temperature changes, but in porous membranes, the constants are independent of, or only slightly dependent on, temperature. Corrections for temperature have been made with certain materials by the use of an equation based on activation energy (Chang and Hutcheon 1956).

$$\mu = \mu_o \exp(-E/RT) \tag{19}$$

where (in appropriate units)

μ_o = constant at $T = \infty$
R = gas constant
E = activation energy
T = absolute temperature

This equation applies to resins, rubbers, and polymers in which the water molecules enter and move through the molecular structure by activated diffusion. It may serve as an approximate solution in other cases.

Equation (19) can be used to construct spot permeability curves for a variety of temperatures if two tests at different temperatures can be run and from which E, the activation energy, can be evaluated. In this way, permeability of material can be estimated from as few as five single tests at carefully selected conditions.

Limitations of Permeance Projections

Other than direct testing for particular conditions, no method predicts effective permeabilities for materials exposed to both a temperature gradient and a humidity (or vapor pressure) gradient, even though this is the usual situation. Data are available on permeances and permeabilities of various materials, but because the data are for different conditions, the results cannot be compared directly. Often, in fact, they do not cover a range of conditions that would permit construction of basic curves of spot permeability or permeance.

The cup test methods are steady-state procedures that may not represent the behavior or reaction of vapor retarding materials under conditions existing in actual buildings. The tests provide a standard means for comparing the permeability characteristics of materials, but measurement techniques for real, dynamic conditions are needed. Table 9, Chapter 22 indicates that some materials show a great difference in permeance for the wet-cup and dry-cup methods. This difference is even more apparent when resistances are noted.

Details of Standard Tests

Since dry-cup and wet-cup tests are easier to carry out than tests at intermediate humidities, most available data have been obtained in this way. The permeance of a material may be judged adequately, for many purposes, if tested by both dry and wet methods. Any statement regarding permeance of a specimen must include test conditions.

ASTM *Standard* E96, Standard Test Methods for Water Vapor Transmission of Materials, gives procedures for measuring water vapor transmission of materials under a variety of test conditions, using both wet-cup and dry-cup apparatus. ASTM *Standards* E398 and F372 describe convenient apparatus for measuring approximate permeance of sheet materials. ASTM *Standard* C677, Practice for Use of a Standard Reference Sheet for the Measurement of the Time-Averaged Vapor Pressure in a Controlled Humidity Space, covers the use of NBS Standard Reference Materials 707-1 (dry-cup) and 707-2 (wet-cup). ASTM *Standard* C755, Practice for Selection of Vapor Barriers for

Thermal Insulations, defines water vapor transmission values appropriate for established criteria.

Units and Conversions

There is no general agreement to follow the method described in this chapter and report results as coefficients of permeance (or permeability, where appropriate) or even to use the same basic units. Test data are frequently reported in terms of mass transmitted per (unit time) (unit area). Such data are referred to as water vapor transmission (WVT) data, and values are either high or low, depending on the vapor pressure difference chosen for the test. When this difference is known, WVT data can be converted to permeance by the following equation:

$$\text{Permeance} = \text{WVT}/\Delta p \tag{20}$$

where

WVT = mass of vapor transmitted, gr/h·ft^2
Δp = vapor pressure difference in test, in. Hg

Table 3 lists common test conditions. Table 9, Chapter 22 presents some data on typical building materials, showing the method and, where applicable, the thickness tested. Note in the table that a paper may be waterproof, *i.e.*, possess water resistance, but still have low water vapor resistance.

PREVENTING SURFACE CONDENSATION

Condensation occurs when water vapor comes in contact with a surface that has a temperature lower than the dew point of that vapor. To prevent condensation from occurring on the warm side of insulated rooms, pipes, ducts, and equipment, insulation should be sufficiently thick to ensure that the insulation surface temperature always exceeds the dew-point temperature.

Figure 12 illustrates the steady-state heat transfer for which the following relationship can be used to calculate the data in Figure 13.

$$q = (t_b - t_p)/R_s = (t_p - t_o)R_i \tag{21}$$

since

$$R_s/R_i = (t_b - t_p)/(t_p - t_o)$$
$$R_i = L/k$$
$$L = kR_i = kR_s(t_p - t_o)/(t_b - t_p) \tag{22}$$

where

q = heat flow rate, Btu/h·ft^2
t_b = ambient still air dry-bulb temperature, °F
t_p = dew point, °F
t_o = operating temperature, °F
R_s = surface thermal resistance, 0.62 °F·ft^2·h/Btu
R_i = insulation thermal resistance, L/k, °F·ft^2·h/Btu
L = thickness, in. (After calculating L, Figure 14 can be used to obtain the actual thickness as needed for pipe insulation.)
k = mean thermal conductivity, Btu/h·ft^2(°F/in)

Table 3 Common Test Conditions

Nominal Test Conditions ASTM E96		% Relative Humidity on Two Sides of Specimens	
Procedure[a]	Temperature, °F	In Cup	Outside Cup
A	73.4	0	50
B	73.4	100	50
C	90	0	50
D	90	100	50
E	100	0	90

[a]Data obtained by one procedure cannot be reliably converted to another procedure.

Equivalent thickness is the thickness of insulation on a flat surface that would be required to give the same rate of heat transmission per unit area of outer surface of insulation, as on a cylinder or pipe.

$$L = r_s \ln (r_s/r_i) \tag{23}$$

where

r_s = outer radius of insulation, in consistent units
r_i = inner radius of insulation, in consistent units

The approximate thickness of insulation L required to prevent condensation on flat metallic surfaces can be obtained from Figure 13, which produces the approximate thermal resistance

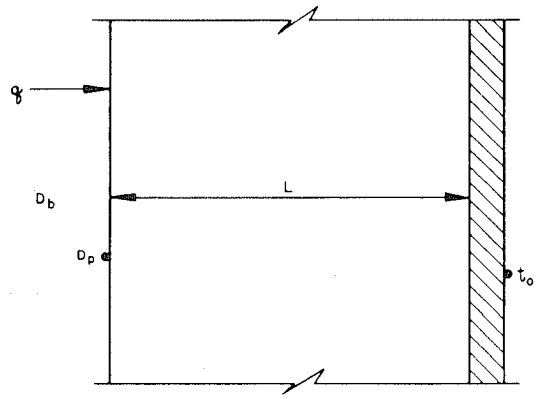

Fig. 12 Steady-State Heat Transfer

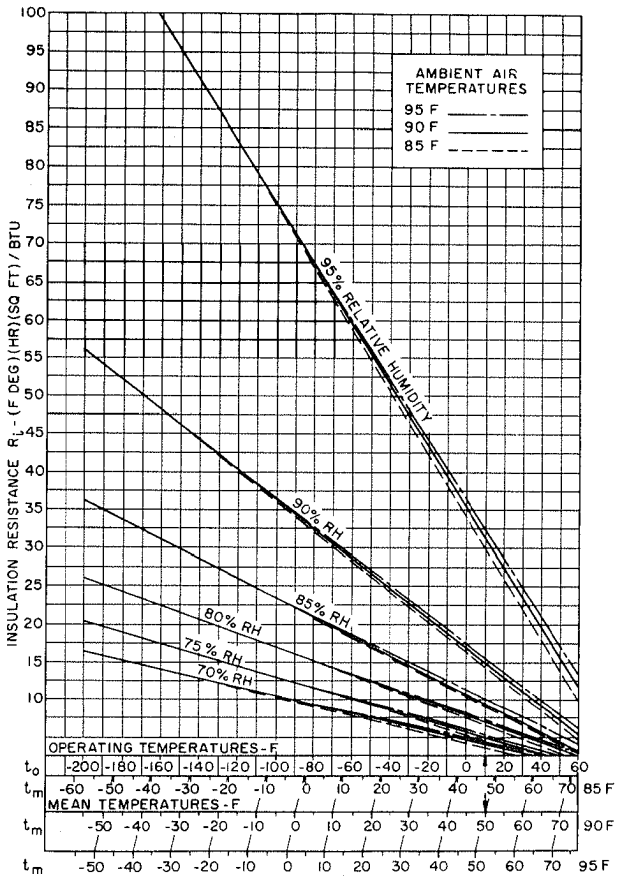

Fig. 13 Thermal Resistance of Insulation to Prevent Surface Condensation

needed to prevent condensation; the formula $L = Rk$ can be used to find thickness. In Figure 13, t_m is the mean temperature for a specific insulating material, and is the arithmetic average of t_b and t_o:

$$t_m = (t_b + t_o)/2$$

A more accurate determination of the insulation thickness L needed to control condensation can be made with the formulas in Figure 12. When pipes are involved, Figure 14 can be applied to relate the thickness of insulation, as determined by either of the methods discussed previously, to the actual thickness needed. By entering Figure 14 with L as the thickness needed on a flat surface (noted as equivalent thickness) and moving vertically until the curve for the pipe size involved is intersected, the actual thickness needed is found by moving horizontally to the Y axis. When choosing pipe insulation, always use the next greater nominal thickness than the thickness determined.

Example 2. A nominal 4-in. pipe operates at 10°F in ambient still-air conditions of 90°F and 90% rh. The mean temperature is 50°F. The insulation specified has a thermal conductivity of 0.28 Btu/h · ft² (°F/in) at the mean temperature, according to manufacturers' tables.

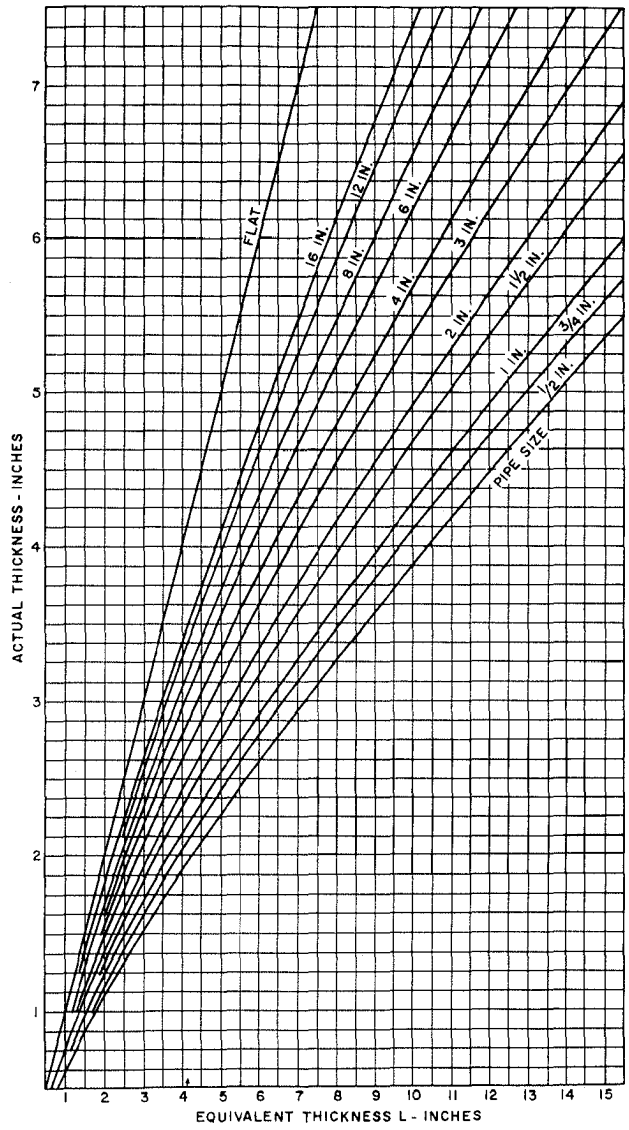

Fig. 14 Conversion of Equivalent Thickness to Actual Thickness for Pipe Insulation

Solution: Using Figure 13, locate the insulation resistance needed to prevent condensation and obtain $R = 14.8$. Since $R = L/k$, the thickness required for a flat surface or the equivalent thickness L for any pipe size is:

$$L = Rk = 14.8 \times 0.28 = 4.14 \text{ in.}$$

To find the actual thickness needed on a 4-in. pipe, read the Equivalent Thickness Scale in Figure 14 from L of 4.1 in. to pipe size of 4 in. and find the actual thickness of 2.9 in. on the ordinate. Select next higher standard thickness of 3 in.

LAND TRANSPORT VECHICLES 21.17
ENVIRONMENTAL SPACES 21.17

THERMAL and moisture design and long-term performance of buildings should be considered in the original planning phase. Adequate insulation installed during construction can be much more economical than later installation. Proper selection of thermal insulations and vapor retarders must be based on:

- Thermal efficiency of the material
- Other physical characteristics required by the location of the materials
- Space available
- Compatibility of the materials with adjacent components.

Types of thermal insulation, their properties, economic thickness, vapor transmissions, and vapor retarder are discussed in Chapters 20 and 22. Insulation in various assemblies that can be used interchangeably for a given construction is discussed in this chapter.

GENERAL BUILDING INSULATION PRACTICE

Wood Frame Construction

Wood frame construction usually includes cavities in walls and ceiling/floor assemblies suitable for insulation. Other horizontal spaces without ceiling finish can also accommodate a fill-type material if it is held in place.

Insulating sheathing placed on exterior walls may also have sufficient structural properties to provide required lateral bracing. Prefinished insulating paneling can be used as an inside finish on exterior walls or on one or both sides of interior partitions; it can also underlay other finishes. A vapor retarder on the winter warm side prevents damaging condensation within the construction.

Structural monolithic insulating decks must be at least 3 in. thick to provide an acceptable overall heat transmission coefficient. Additional thermal insulation can be placed on top of or below the deck. Roof/ceiling construction that does not have a ventilated air space may allow water vapor to condense in it. To control this potentially damaging condensation, a vapor retarder may be needed at or near the inside surface. In any case, roof decks of wood, metal, or preformed units requiring additional high thermal resistance insulation may require a vapor retarder depending on weather conditions.

The preparation of this chapter is assigned to TC 4.4, Thermal Insulation and Moisture Retarders.

Conventional attic construction with rafters and ceiling joists can be insulated between framing members with batt, blanket, reflective, or loose-fill insulation. A vapor retarder on the winter warm side of the insulation helps maintain the desired humidity within an interior environment. Batt and blanket insulation with an integral vapor retarder is adequate if properly installed.

Attics are usually vented to limit condensation and to reduce the attic temperature from solar radiation. Figure 1 shows a combination of eave and soffit vents with gable-end vents in an insulated building with knee walls. Roof vents or ridge vents can also be installed to vent attic spaces. Note that the floor joists under the knee wall are blocked to keep cold air from flowing under the finished attic floor.

Preformed metal framing members may be installed in a similar way to wood frame construction, except that physical dimensions of and spacing between members may differ. Preformed insulation material of the proper dimension may be installed if loose-fill or sprayed-in-place insulation is not used.

Existing frame construction can be insulated pneumatically, using suitable loose insulating material that can be applied in this manner. Accessible space can be insulated by manual placement of batt, blanket, or loose-fill material.

In cold climates, the vapor retarder must effectively prevent vapor movement into the roof/ceiling space by diffusion or air flow. Note that air moisture may also enter the roof through openings in the wall, *e.g.*, electrical outlets, finding its way through the plate and into the roof.

Steel Frame Construction

The steel framing usually supports the building. The exterior metal cladding or curtain wall provides no structural support. This type of structure is usually insulated between the frame and cladding with faced blanket or spray insulation as shown in Figure 2. The facing often serves as a combination vapor retarder and interior finish and must be protected against physical damage.

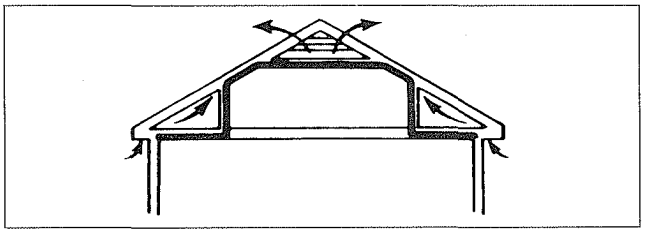

Fig. 1 Location of Insulation and Vents for Finished Attic Spaces

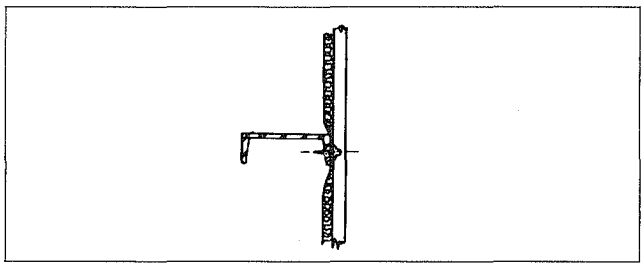

Fig. 2 Steel Frame Building Wall Insulated with Flexible Blanket

Other types of insulation can be used by adding framing or furring to the inside of frame or weather covering. This type of installation should also have an interior vapor retarder. Securing insulation as shown in Figure 2 causes local reduction of thermal resistance. This reduction plus the thermal bridging caused by the screw or bolt penetrating the insulation to the interior skin may result in condensation during cold weather.

Curtain walls may be (1) custom walls for specific projects, where most construction components are developed on a one-time basis; (2) commercial walls, where standard components are adapted to a particular building design; and (3) industrial-type walls, where standard metal sheets are fluted or ribbed to form field-assembled sandwiches to meet job conditions.

Curtain walls may consist of prefabricated panels or sections that can be classed as one of the following general types:

1. To withstand the elements, single-thickness facings are usually inserted in subframing with the windows to form a veneer over separate backup walls. Thermal insulation is integral with, or added to, the exterior of the backup wall and covers the edge of the floor slab or spandrel beam. This method reduces heat loss and keeps floors warm at their exterior edge. Insulating the exterior of the framing reduces thermal movement of the building structure (Figure 3).
2. Sandwich construction or adhesive-bonded panels are generally of three-ply construction: exterior skin, core materials, and interior skin. This type of panel, when manufactured with concrete faces and an insulation core, comes in large sizes and can be attached directly to the exterior of the building frame. When using metal facings, the width of the panels is usually restricted to match that of the standard formed sheet. These panels are installed on the exterior of the building framing. The thermal performance required for a particular installation should be carefully checked because adding insulation later is difficult.
3. Mechanically fastened panels are generally the hollow box type, with the exterior facing nesting over the interior facing. The cavity can be filled with flexible or semirigid insulation (Figure 4). The edges should vent to the exterior of the building. The panels are normally installed in a subframing system.
4. Industrial metal panels have an exterior facing of standard ribbed, corrugated V-beam materials and an interior facing of proprietary metal pans or standard corrugated or ribbed sheeting (Figure 5). Insulation varies from semirigid to rigid, depending on the design of the inner surfacing materials. It provides good thermal and moisture control when installed with tight inner surface construction.

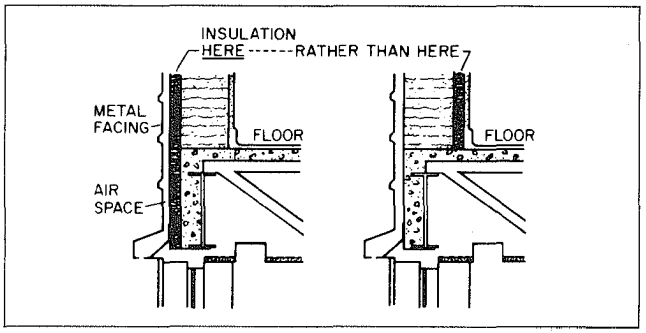

Fig. 3 Proper Placement to Insulate Structural Frame

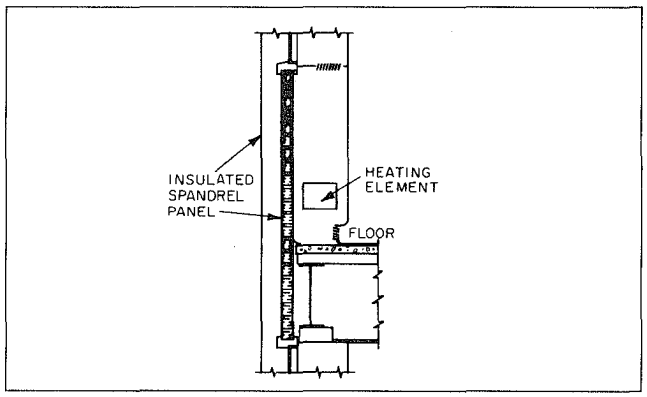

Fig. 4 Insulated Pan-Type Panel

All curtain wall panels with insulation in the cavity or as a core should be sufficiently tight at their edges to prevent the entrance of free water or moisture. However, because some moisture may penetrate the vapor retarder and enter the wall, the exterior component should be porous enough to allow moisture vapor and air to escape. Panel edges should not be hermetically sealed. For cold climates, the subframing members or wall mullions should be of noncontinuous construction. The exterior to interior path should have a thermal break or insulated mullion cover on the interior (see Figure 6) to reduce the hazard of condensation.

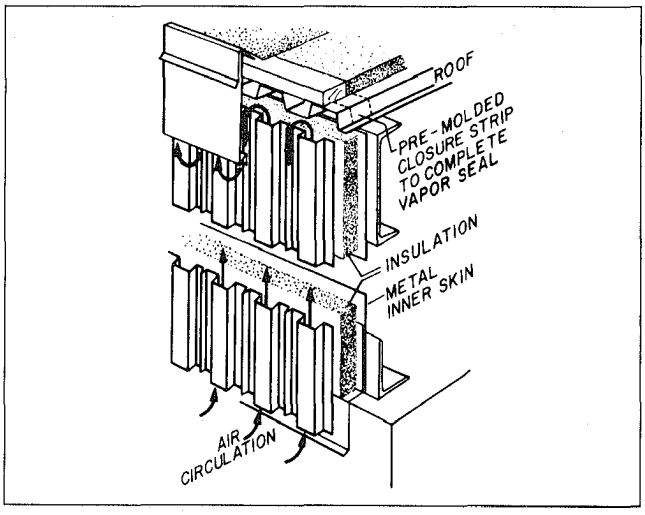

Fig. 5 Vented and Insulated Field-Fabricated Curtain Wall

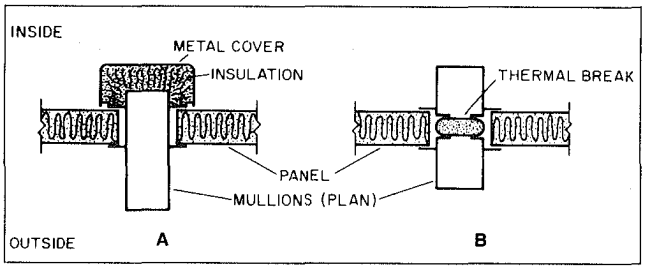

Fig. 6 Methods of Reducing Thermal Conduction through Mullions

Masonry Construction

Because concrete masonry unit walls and masonry cavity walls have hollow vertical cavities, insulating materials can usually be placed within the wall itself. Loose-fill insulation, such as water-repellent perlite and vermiculite, as well as newer foam inserts and foamed-in-place insulations, are commonly used. This insulation method is most effective with low-density masonry units. Rigid insulation can be placed between the wythes in a cavity wall or veneered construction (Figure 7A), and furring on the inside of the wall is still used in many areas (Figure 7B).

The thickness and density of concrete masonry wall construction coupled with its interior air cavities moderate the heat transmission through such an insulated wall construction. The thermal mass or inertia of such heavy construction causes a time lag of heat migration, which may lower the peak gains or losses. Insulation placed on the outside of a concrete masonry wall can also enhance this heat storage, time lag effect and help protect the structure from expansion and contraction caused by temperature extremes.

Resistance to moisture penetration in masonry walls depends on wall construction. For cavity wall construction, metal flashing at each floor and roof intersection collects and diverts moisture out through weep holes in the masonry wall. For through-wall construction, waterproof coatings of portland cement, latex, or oil-base paints are used, as well as epoxy, silicone, and bituminous based coatings. Depending on the severity of the moisture problem, both filler and finish coats can be used. Manufacturers' suggestions should be followed in such applications. Fill coats (fillers or primer-sealers) fill voids in coarse-textured masonry units and help smooth out surface irregularities before application of finish coats. Whatever the construction, tooled concave or V-shaped mortar joints are preferred. These joints impede moisture infiltration because the joint tool compresses the mortar and forces it into holes or voids that may develop when laying the concrete masonry units. They also create a shape that sheds water.

In addition to augmenting effective thermal performance, proper insulation can enhance the characteristic fire resistance and noise-reduction qualities of masonry construction. Also, insulation materials installed during construction and integral with the wall are usually placed by the mason, resulting in reduced construction time and a more economical structure.

Precast or poured-in-place solid concrete walls are insulated similarly to solid masonry construction. The design and method of fabricating the panels dictates the type of insulation selected. Figure 8 details the joint of a typical precast concrete panel with sandwiched insulation.

Floor Systems

Perimeter insulation should be applied vertically on the inside (Figure 9A) or outside (Figure 9B) of foundation walls. Rigid mineral fiber or cellular plastic insulation are used as perimeter outside insulation (Figure 9B). Drainage (*e.g.*, gravel-fill wire mesh) may be required by manufacturers for some perimeter insulations. It may need protection from physical damage if it extends above grade level. Insulation can also be installed horizontally under the slab, from the foundation wall inward for a distance of 2 ft or more, often with vertically placed insulation.

Below-grade, back-filled walls enclosing usable and heated space can be insulated and finished in the same way as solid masonry or concrete walls. Unoccupied and unheated spaces below heated areas, such as crawl spaces, may have insulated walls to maintain crawl space temperatures and minimize the need for underfloor insulation. A ground cover vapor retarder should be used, particularly over moisture-bearing soils. The soil should be graded to drain the crawl space so that surface water will not rise above the vapor retarder. Floor insulation eliminates the need for dampers on crawl space vent openings, but does not allow these spaces to be used for utilities or a heating distribution system unless it is efficiently insulated.

Floor construction with joists can be insulated between the joists (Figure 10). Insulation between joists must have supplemental support. Material with an integral vapor retarder, installed with the vapor retarder up, can be secured by the flange provided for this purpose. Laced wires, barbed-end wires spanning the joist space, wire mesh, screening, or ceiling finish will support loose-fill insulation. Floor construction can also be insulated by placing flexible blanket material over the joists before laying the subfloor.

Another floor insulation method uses double-sided, perforated aluminum foil draped and stapled over floor joists (BRANZ 1983). For about a 4-in. sag depth, laboratory R-values were 5.7 to 14.2 °F·ft²·h/Btu with a mean of 6.8, depending on the humidity above the floor space. Field measurements have shown R-values up to 14 °F·ft²·h/Btu for carpeted floors over good installations with a 4-in. sag.

Roof Deck Construction

Almost all structural roof deck construction systems require thermal insulation to economically maintain the design indoor environment. For level or nearly level roofed structures, insulation should be placed on top of the deck, on the outside of the structure. This location moderates the deck temperature, which reduces thermal movement of the deck and the potential for underdeck condensation. Traditionally, the insulation is placed under the roof membrane so that it functions as a base for the built-up roof (BUR) membrane. For a stable base, a good bond must be established between the insulation, through the vapor retarder, to the roof deck, and between the insulation and the BUR. Ineffective bonds that allow the BUR to move in reaction to stresses from temperature changes often cause the roof to fail.

In this configuration, a vapor retarder should be placed between the deck and the insulation when required by interior environmental conditions. An alternate method for obtaining the required vapor retarder for a solid-shaped metal deck is to seal the deck at all overlaps and joints.

Single-ply membrane roofs are frequently installed with ballasted, loose-laid, or mechanically fastened systems. Adhesion to the insulation is usually not desirable.

Insulation can also be placed above the membrane in a Protected Membrane Roof (PMR) system. With this approach, the roof membrane is installed on the deck, where it functions as a waterproofing membrane and vapor retarder. Insulation can be placed above and below membranes to function both as the base for the membrane and the membrane protector, as well as for the insulator. Some insulation can be wetted and then successfully dried; while wet, however, it has a greatly reduced insulation value.

Roof systems designed for continual heavy traffic should have a secondary structure, supported on a curb system, above the water membrane of the roof system.

Insulation for pitched roofs covered with shingles, tile, or similar mechanically fastened watershedding materials should be placed above the ceiling directly on the attic floor. A vapor retarder should be placed on the winter warm side of the insulation, and the attic space must be adequately ventilated.

If the undersurface of the pitched roof is exposed to the interior, the winter warm side vapor retarder and insulation can be applied over the roof framing or decking. The insulation is then covered with a nailing base for the roofing application. Prefinished roof planks with the required thermal resistance can also be placed over the rafters.

Ventilation may be needed between the insulation and the roofing nailing base depending on the influence the permeance of the insulation and vapor retarder has on interior environmental conditions.

If insulation must be placed on a suspended ceiling, the space between the insulation and roof deck must be adequately ventilated for condensation control. Power-driven ventilators are usually necessary for flat decks. The ventilation air must come from the outside. It is important to use effective air and vapor retarders.

INSULATION FIELD PERFORMANCE CHARACTERISTICS

Convection and air infiltration in some insulation systems may increase the heat transfer across them. Low-density loose-fill, large open-cell, and fibrous insulations and poorly designed or installed reflective systems are most susceptible to increased heat transfer caused by natural and forced convection (air infiltration). A change of temperature differential across an insulation, as well as the height, thickness, or width of the insulated space, influences the amount of convection. When an impermeable membrane is applied to one surface or when the cavity is filled with insulation, natural convection is reduced significantly and apparent thermal conductivities measured by standard test methods apply.

The effectiveness of thermal insulation is seriously impaired when it is installed incorrectly. For example, a 4% void area in R-11 $ft^2 \cdot °F \cdot h/Btu$ wall insulation increases heat loss by 15%. A 4% void in R-19 ceiling insulation causes a 50% increase in heat loss. When insulation is properly installed, the wall or ceiling system performs as shown in Table 4, Chapter 22. Verschoor (1977) found that air interchange around thin wall insulation installed vertically with air spaces on both sides increases heat loss by 60%. Other factors, including vibration, temperature cycling, and other mechanical forces, can affect thermal performance by causing settling or other dimensional changes. Section A3 of the CIBSE Guide (1986) gives more information on the effect of moisture on thermal properties of building structures.

MOISTURE IN BUILDINGS

MIGRATION OF WATER VAPOR

Importance of Air Leakage

Vapor retarders have been advocated to avoid condensation problems in buildings, since water vapor migrates by diffusion through the building envelope materials because of a vapor pressure difference. Typical winter indoor vapor pressure at 70 °F and 40% rh is about 0.13 psi above outdoor vapor pressure when the temperature is 0 °F. Wilson and Garden (1965), Dickens and Hutcheon (1965), Latta (1976), Handegord (1979), Tamura (1975), and Chapter 23 show that air movement carrying the water vapor with it is far more powerful in transporting water vapor within the building envelope. Condensation will occur if the air/vapor mixture is cooled to its dew point and latent heat is removed.

Air passing quickly on a direct path through a wall may not be cooled sufficiently to condense until it mingles with and is diluted by the outdoor air. Air following a longer path on the cold side of the insulation (for example, when it flows down an air space to escape at weep holes) may deposit water on the back of a cold cladding or sheathing.

The relative amounts of water deposited in a wall or roof by vapor diffusion or by a current of air cannot be calculated with certainty. Under one set of conditions, six or seven times as much water can be deposited as a result of air leakage as by vapor diffusion through a wall without a vapor retarder. Under different circumstances, the rates could be 100:1 or higher.

A good quality vapor retarder eliminates condensation by vapor diffusion, but even an excellent vapor retarder is of little benefit if it can be bypassed by a current of air. Therefore, the first defense against condensation is control of humid air movement within a building structure by airtight construction. The section on concealed condensation in this chapter and the section on water vapor retarders in Chapter 20 include further details.

Water entering between two layers with high resistance to vapor diffusion may damage the construction if it does not dry out again. As a result, the double vapor retarder compounds the problem initiated by the defect that allowed the water to enter. Walls and roofs should be designed so that any water that enters can be removed by ventilation or by drainage to the outdoors or to a location capable of withstanding the water. Drainage may not be sufficient in low-slope roofs and is addressed in the section Membrane Roof Systems.

Controlling Air Movement

A controlled amount of ventilation air must be provided to remove moisture, but removal should not be left to uncontrolled air leakage. To control air leakage, either the holes through which

the air passes or the driving pressure difference must be eliminated. Since the pressure differences arise from the natural phenomena of wind, air, and temperature differences, they can only be balanced by changing the pressure inside the building. However, the complex controls and equipment needed to sense and balance the pressure difference under constantly changing conditions make this solution impractical. The most practical approach is to minimize the size and number of holes.

It may be simple to design a satisfactory wall or roof construction for clear uninterrupted areas, but intersections with other building components require planning to link the airtightness of a wall section to the airtight glass in a window or an airtight membrane in the roof or ceiling. Leakage paths are often found in the inside of the outer wall where a partition wall joins it. Similar leakage paths can be found in electrical outlet boxes, at openings for piping, up through the hollow core of a partition wall, and through the ceiling, if ceiling airtightness is not carried across the top of the partition. A designer should work closely with construction workers to find practical solutions to construction problems, but in considering alternatives, airtightness of the envelope must be maintained.

Airtightness and Location of Air Barriers

In striving to eliminate air leaks, but realizing that perfection is not attainable, construction should include drainage or ventilation to carry away unwanted water. Ventilation or drainage must go to the outside of the airtight layer of construction or it will increase air leakage of the building. To avoid condensation on the airtight layer, the layer must either be kept above dew point by locating it on the warm side of the insulation or be of adequate permeance to permit vapor to move to the outside.

There must be no gaps between the airtight layer and the insulation, or cold air will penetrate the ventilation or drainage openings into the warm side of the insulation and reduce its effectiveness. Generally, the air barrier is placed on the warm side of, and in contact with, the insulation. The air barrier must be sufficiently strong and well supported to resist wind loads.

Air leakage through the building envelope does not necessarily occur at doors and windows. Tamura and Wilson (1964) showed that leakage from windows and doors in houses constitute only about 20% of the total leakage. Leakage cracks and openings in walls and ceilings, especially at intersections of walls, floors, and ceilings, make a far greater contribution to total leakage. Depending on the particular house, up to 70% of the total leakage openings was in walls, and up to 67% was through the ceiling.

Holes for wiring or plumbing in upper plates of exterior walls and interior partitions may cause about 50% of the total leakage through the ceiling. An equivalent leakage area may develop from shrinkage of upper wall plates after construction. Substantial leakage openings can be caused by wood shrinkage or cantilevering of floor constructions at the foundation wall or second-floor level. Chimney or plumbing stack penetrations and access hatches or fans are also likely leakage locations. In some residential construction, more leakage has been found between a window frame and wall than between a window frame and sash. Unsealed joints in ductwork and around exhaust fan openings are also common leakage areas.

Not all cracks and openings can be sealed in existing houses, nor is absolutely tight construction achieved in new housing. However, an effort should be made to provide as tight an enclosure as possible to reduce leakage and so minimize potential condensation within the envelope. Such measures also reduce energy loss.

Air Leakage in Buildings

The direction and rate of air leakage through cracks and holes depends on the direction and magnitude of air pressure differences created by stack effect and wind, and by the action of chimneys, fans, and blowers. Most significant is the stack effect from the winter temperature difference between inside and outside. Warm inside air, lighter than cold outside air, rises and flows outward through cracks and openings in the upper walls and ceilings. Condensation occurs on contact with cold surfaces below the dew point. The magnitude of the pressures depends on the height of the heated space and the temperature difference, as indicated by Equation (9) and Figures 1 and 2, Chapter 23.

Air pressure differences created by wind may be of the same magnitude as those of stack effect for low-rise buildings in cold climates (see Figure 3, Chapter 23). Wind pressure acts inward over the windward walls and outward over leeward walls and walls parallel to the wind. Although suction pressures are generally created over all flat or sloped roofs, the sustained pressure difference from wind across the ceiling in a ventilated roof space is usually near zero.

Electrically Heated and Fuel-heated Houses

In electrically heated houses or houses without a chimney, the midwinter pattern of pressure differences from average wind and stack effect is likely to be similar to that shown in Figure 4, Chapter 23. Outdoor air leaks inward through windward walls, while room air leaks outward through the ceiling and leeward walls. The pressure acting upward across the ceiling is caused primarily by stack effect; it acts in this direction as long as the inside temperature is higher than the outside. Thus, a constant pressure moves indoor air up through the ceiling.

This upward air pressure difference is counteracted or even reversed by the burner and chimney of a house with a fuel-fired heating system (Tamura and Wilson 1964). The stack effect of an operating chimney is greater than that of the house, because the flue gases are at a much higher temperature. Unless the combustion chamber has a source of outdoor air, the chimney acts like an exhaust fan, lowering the interior air pressure. In this case, the pressure difference across the ceiling is reduced, but the pressure difference acting inward is increased and acts over a larger total area of inlet openings. The total air change rate is thus increased, with most or all of room air exhausting through the chimney with the flue gases rather than into the cold wall and roof spaces.

The furnace chimney represents the most significant difference between electric and fuel-heated houses as far as air leakage and indoor humidity levels are concerned, since it provides an exhaust opening when the burner is off. A fireplace is comparable to a furnace chimney, unless combustion and ventilation air are taken directly from outdoors.

Tolerance of Condensation

As climatic conditions change with the seasons, limited condensation that accumulates at one time can dry out at another. To a lesser extent, diurnal drying can occur from solar heat gain. If the material on which condensation is deposited can temporarily store the quantity of water involved, no harm may result. However, this will not always be the case; each wall or roof should be assessed individually. Refrigerated storage or insulated chilled water pipes, where conditions do not change with the seasons, are examples of situations where condensation does not dry out.

Some materials can temporarily store water without damage. Assume that during one month, 1 lb of water is deposited by diffusion in a single concrete block with an absorptive capacity from dry to saturated of 10 lb. If the block is initially at 40% saturation, this extra water can readily be absorbed by the inner face, raising saturation to only 50%. This quantity of water would probably go undetected.

Wall components with little or no absorptivity, for example metal panels, could collect appreciable quantities of such surface condensation as frost or ice that can be rapidly released with a change in weather conditions. Any water vapor passing through

an inadequate or defective vapor retarder in an unventilated flat roof with a highly impermeable exterior membrane will be trapped between the two layers, leading to premature roof failure.

CONDENSATION IN HEATED BUILDINGS

Unwanted moisture accumulation in heated buildings may be caused by either visible or concealed condensation. Each location of condensate requires different control strategies, either active or passive. Active condensation controls attempt to limit, by controlling moisture sources and mechanical equipment, the quantity of moisture present. Passive controls attempt to limit moisture migration, retard unwanted accumulation, and accelerate disposal of condensed moisture with combinations of construction materials and schemes that take advantage of natural forces or mechanisms, such as vapor retarder systems and natural cavity ventilation.

Indoor Humidity Levels

The moisture content of the air in a heated building in winter is higher than that in the outdoors, because moisture is introduced by occupants, processes, or humidification equipment. Actual building humidity depends on the balance between the rate at which it is lost by diffusion, air leakage, ventilation, and condensation. Table 2 in Chapter 20 of the 1992 ASHRAE *Handbook—Systems and Equipment* gives rates at which moisture is supplied by the occupants and their activities. Moisture loss by diffusion depends on the water vapor permeance characteristics of the building envelope materials and the vapor pressure difference across the envelope. Moisture lost through air leakage depends on the air pressure differences and the characteristics of the envelope leakage openings.

Flow rates due to natural ventilation can be estimated from the data in Chapter 23, and flow rates due to mechanical ventilation can be calculated from design data. The accuracy of these calculated estimates depends on whether the number, size, and location of openings are known. Condensation on surfaces exposed to the building interior is normally minimal and can either be eliminated by improved thermal design of the enclosure element or by intentionally lowering indoor humidity.

Lowering indoor humidity to minimize surface condensation on windows is one approach, but increasing the interior surface temperature of the window by multiple glazing may be more effective. Multiple glazing has the added advantages of saving energy, improving occupant comfort, and reducing the possibility of condensate damage to the interior adjacent to the window, *e.g.*, staining of wall, rotting of window sill, and mold growth. Both humidity reduction in the space and additional glazing involve additional cost. Lowering indoor humidity enough to avoid concealed condensation within insulated construction may be difficult or impossible in areas with extremely low dew points. For example, with a sheathing temperature of 5 °F, indoor air at 70 °F is limited to a relative humidity of 6% if the indoor air comes in contact with the sheathing. However, experience suggests that lowering indoor humidity enough prevents potential condensation damage, even though occasional condensation may still occur.

In houses without chimneys or fireplaces, moisture from normal occupant activity may raise humidities to cause excessive condensation on windows. With fuel-fired heating systems, however, ventilation by the chimney in conjunction with air inlet openings often maintains relative humidity levels below that for window condensation (particularly with multiple glazing), except in extremely cold temperatures.

Control of Excess Indoor Humidity in Houses

The relative humidity maintained in heated buildings is usually determined by the requirements of the occupants, but it may be limited by visible condensation on surfaces exposed to the space. If improved thermal performance of the component is not possible, the removal of moisture sources such as humidifiers or attached greenhouses should be considered. Exposed soil surfaces in crawl spaces or cellars should be covered with vapor retarder membranes held down by sand, gravel, or other suitable means. Houseplants are a source of moisture, as is green or wet wood stored inside for fuel. (See Chapter 20, Table 2, in the 1992 ASHRAE *Handbook—Systems and Equipment*.)

Visible condensation may be removed in several ways. An exhaust fan controlled by a humidistat setting causes dry and cold outdoor air to infiltrate, flushing out moist air. An air-to-air heat recovery device can be included to reduce the heating energy penalty from the exhaust fan. Devices that also recover latent heat may be counterproductive if the moisture is reevaporated into the incoming airstream. Other approaches include the use of mechanical dehumidifiers and insulated vent stacks that go from the living space through the roof. The use of dehumidifiers should be taken as an indicator that greater precautions for moisture control may be required.

Short-term ventilation procedures, such as occasionally opening a window or door, may lower humidity momentarily, but it will rise to its original level soon after the opening is closed. Materials such as wood, fabrics, paper, and rugs absorb water vapor from the air until their moisture content is in equilibrium with the relative humidity. This slow process can remove substantial quantities of water. When relative humidity is reduced, the absorbed moisture slowly evaporates from the material over several days or even weeks. The slow evaporation of moisture accumulated over a summer of high relative humidity is the reason houses have a high relative humidity in the fall.

Windows and doors are not a satisfactory means of ventilation in very cold weather. If there is no other alternative, houses with forced warm air systems can use an outdoor air intake duct with an adjustable damper for continuous ventilation. The chimney acts as an exhaust outlet for room air and combustion products. In this arrangement, the furnace circulating fan should run continuously to control the distribution of outdoor air entering the system. Alternatively, an automatically controlled damper may be installed in the outdoor air duct. The duct should be insulated to avoid condensation on its surface in cold weather. Although this ventilation system can be very effective in reducing humidity, extra energy is needed to heat the additional outdoor air. Also exfiltration increases, and concealed condensation may occur. This alternative should be used only as a last resort to control a serious moisture problem.

VISIBLE CONDENSATION

Figure 11, Chapter 20 in the 1992 ASHRAE *Handbook—Systems and Equipment* shows combinations of indoor relative humidity and outdoor temperature levels at which visible condensation appears on surfaces. Because wall surface temperatures vary with other factors, such as the presence of thermal bridges and circulation or stratification of room air, the values indicated are only an estimate. Condensation will take place at any sufficiently cold spot, and the limit on indoor relative humidity levels for control of visible condensation on a nonhomogeneous wall generally is lower than may be inferred from its average U-factor.

Danger of Surface Condensation

On surfaces that remain only slightly above dew point and where condensation is barely avoided, the average moisture content may still be high enough for noticeable discoloration, mold growth, and dimensional change. Such surfaces are often in poorly ventilated closets and behind furniture against outside walls. The effects of thermal bridges on moisture and dust accumulation are

indicated by further discoloration of drywall surfaces over nail heads and framing members. A similar phenomenon may also be observed on the outside surfaces of heavily insulated walls with insufficient thermal break over the studs. As the cavity is better insulated, the exterior wall surface between studs stays colder and has a higher rate of dust accumulation than that directly over studs. The dust marking becomes evident through more rapid discoloration over colder surfaces. Siding may become more vulnerable to mold growth (Neilson 1940). An International Energy Agency (1990) study concluded that the critical monthly mean surface relative humidity is 80% for mold growth on interior building surfaces.

Summer Surface Condensation

Surface condensation on below-grade concrete and masonry walls and floors is a common problem in areas with high summer humidity. Heavyweight construction has a more nearly constant surface temperature close to the soil temperature, while air dewpoint temperatures fluctuate from day to day. Mechanical or chemical dehumidification and selective ventilation during periods of low dew point are used to prevent surface condensation. Unless preventive measures are used, surface condensation may deter the successful application of earth-sheltered design concepts based on radiant cooling.

One means of summer surface condensation control is added insulation with a vapor retarder on the warm side, such as that used in the insulation of cold water pipes. Insulation on the outside of basement walls helps control condensation on the interior surface by isolating the walls from colder ground temperatures. Insulation on the room side eliminates visible condensation but can foster concealed summer and winter condensation.

Floor Slab Condensation

Summer surface condensation may also form on concrete floors on grade. Carpeting tends to lower the interior slab surface temperature, increasing the condensation hazard. Dehumidification and ventilation may be sufficient to control odors caused by the moisture; these are generally more objectionable than actual damage to the floor covering.

Entry of ground moisture can be reduced by isolating the slab with the placement of a low-permeability membrane over the soil, beneath the slab, and using coarse gravel to break the capillary moisture rise. Note that application of a membrane is difficult because of the potential damage during construction.

Sealing of floor slabs and basements against the entry of radon should also be considered. Although soil cover sheets are commonly referred to as "vapor retarders," they can also act as a waterproofing membrane when exposed to liquid water.

Control of slab surface temperatures is an important consideration in minimizing the need for mechanical dehumidification, particularly with solar-oriented designs that emphasize the effects of thermal ballast. In localities with severe summer surface condensation problems, lightweight concrete should be considered for floor slabs to increase their insulating value or insulation under the slab.

Preventing Surface Condensation

Low air infiltration or ventilation increases the winter condensation hazard because higher indoor relative humidity levels are sustained. The design expedient controlling condensation by warming cold window surfaces with warm air or radiation may not be compatible with energy conservation objectives.

Multiple window glazing based on the outside design temperature should ensure that windows remain clear most of the time. Based on the U-factors given for the center of glass in Chapter 27, comfortable inside conditions can be maintained without excessive window condensation on double-glazed windows with outside temperatures down to 5 °F and on triple-glazed windows with outside temperatures down to −28 °F. In both instances, some condensation may appear around the edge of the window perimeter but should disappear with a warming trend. This criterion should be used in deciding whether to install double or triple glazing to maintain the desired humidity, or whether to reduce humidity to avoid condensation during the coldest periods.

CONCEALED CONDENSATION

Condensation Control Strategies

Most buildings are maintained for human occupancy by managing relative humidity in the 30 to 50% range. In parts of healthcare facilities (such as operating and intensive care rooms) and other buildings, higher relative humidities may be required. Concealed condensation control is based largely on passive control measures. Such measures may vary between residential and commercial or institutional buildings because of variations in scale and in construction details. Nevertheless, the basic control strategies are the same.

Since complete control of air and vapor flow is not feasible, moisture accumulating in structural cavities must be disposed of by ventilation and drainage. Disposal provisions must be outside the airtight layer in the construction, or they will increase the total air leakage of the building. This concept is known as the flow-through principle. Furthermore, the air infiltration barrier should be kept warm by placing it on the warm side of the insulation or it must be designed to allow moisture egress. Since the insulation cannot be relied on to be airtight because of its inherent porosity or imperfectly sealed joints, the airtight layer should be placed in contact with the insulation to preclude convection airflow from the room. If so installed, the layer will perform the functions of both air barrier and vapor retarder.

Water vapor and airflow control in a single plane also prevents trapping condensed moisture in a cavity. Water lodged between two impervious layers can rapidly degrade materials.

Control in Residential Construction

Wood frame roofs may be more vulnerable to decay than are frame walls, possibly because of the higher moisture flow rate through defects in the ceiling vapor retarder and insufficient ventilation. Poorly ventilated spaces (behind knee walls, for example) and defects in the ceiling vapor retarder (recessed lights) are typical areas of concern. Particularly troublesome are poorly fitted bathroom exhaust ducts penetrating poorly ventilated flat roof cavities. Damage may also develop in structures with a year-round moisture source, such as swimming pool enclosures, without sufficient protection and ventilation.

An attic space can be ventilated at a sufficient rate to assure satisfactory moisture dissipation. In areas of heavy snowfall, a cold roof surface is also needed to prevent the snow cover from melting on the roof and forming ice dams along the eaves. Reducing the total available vent area during the coldest months may conserve energy without condensation damage, as long as adequate moisture dissipation is still allowed.

The effectiveness of attic ventilation varies with climatic conditions, especially wind. It may be most beneficial in continental climates where, on a sunny day, the daytime outdoor relative humidity decreases with rising temperatures. In coastal climates its effectiveness may be reduced, as experienced in Great Britain. Dickens and Hutcheon (1965) considered attic ventilation a less reliable moisture control measure in Canadian climates than it is in the United States.

In level roofs, free air must circulate through all joist spaces from one eave or soffit to the other. Obstructions such as header beams cannot be effectively bypassed; therefore, vent stacks placed on a raised curb in the middle of the roof should vent the joist

spaces. Similar details may also be necessary in construction with soffit vents placed below the plane of the roof, as in mansard roof design. In such cases, the ventilation air must flow down the vertical chase. Since the wind force may not be sufficient to overcome the thermal stack effect, this may lead to stagnation of warm and moist air in the flat roof cavity.

Sloped roofs offer several advantages in residential construction. Water vapor gained in the roof cavity can be dispersed in a larger volume of attic air and may be absorbed in a larger wood sheathing surface. Although the condensation may be localized or distributed, condensed water can cling to the sheathing and drain down to the perimeter soffit, where it may be disposed of by appropriate flashing or other drainage provisions. In flat roofs, condensation forms immediately above leakage openings and usually finds its way back into the house through the same openings.

Cathedral ceilings built with joists are vulnerable to moisture problems similar to those for flat roofs; they can, however, be provided with ridge vents and drained through soffits or eaves. Cathedral ceilings built with plank decking exposed to the interior appear to have a sufficiently high moisture capacity to withstand typical heating season moisture accumulations. In more heavily insulated construction, a superior vapor retarder with a rating not greater than 0.1 perm is necessary between the deck and the insulation. The best construction practices also favor separation between insulation and roofing (sheathing on sleepers) to permit ventilation at that plane.

Moisture dissipation from wood frame wall cavities can be accelerated by solar gain which drives moisture accumulated on the sheathing back into the cavity and out through available vent openings. In severe climatic conditions, such ventilation effects may not be sufficient, and further provisions may be needed for positive drainage at the bottom of the cavity. A single weep hole in each stud space should allow sufficient outward drainage of moisture without promoting excessive circulation of outside air in the wall cavity. At the same time, such weep holes should be large enough to prevent rapid freeze-up and blockage by insects.

Control in Commercial and Institutional Construction

Materials commonly used in commercial and institutional construction tend to be somewhat more moisture-tolerant and decay-resistant than those used in residential construction. In addition, vapor retarders in the walls of commercial buildings are less common. As a result, air leakage through hollow concrete masonry is often greater than in other types of construction. Upward airflow in the cavities is not always adequately blocked, and parallel random leakage paths are found between gypsum wallboard or other finishes and the block face. Because of such conditions, plaster or heavy-textured paints and mastics that fill the pores and holes control airflow better than do sheet materials.

Air can leak through exterior walls where the structural system or services penetrate the air barrier or at joints between dissimilar materials or components. For example, masonry cannot form a tight seal with structural steel columns and beams. To reduce this problem, the structural frame should be inside and separate from the exterior wall. The resulting curtain wall can then incorporate a more continuous air barrier and be protected from the fluctuating weather by insulation applied to the outside. Exterior cladding to control rain penetration is best applied following the weather-tightening system. The interior wythe (masonry course) and air barrier should be accessible for maintenance of the air seal and joints.

The deterioration of exterior structural elements of a building and damage to the interior through condensation from air leakage have an important bearing on the operation and maintenance costs of the building. Improving the airtightness of internal floors and partitions, particularly in high-rise buildings, redistributes the pressure differences caused by stack effect and reduces the pressure difference across the exterior wall on each floor. This approach also improves ventilation and air distribution and reduces the air circulation between occupancies on different floors. It also helps control smoke movement in the case of fire and may enable a more equitable apportioning of energy charges for space heating between individual units in apartment buildings.

Leakage in actual buildings often occurs through holes cut accidentally or deliberately in a reasonably tight membrane or component, such as the penetration of services through specified air or vapor retarders or solid components. Other leakage openings in the exterior envelope result from dimensional changes in improperly placed materials or by inadequate sealants or membranes applied to bridge joints or cracks that will eventually open.

Membrane Roof Systems

Since most membrane roof systems in commercial and institutional construction are highly resistant to vapor leakage, condensation must be prevented when insulation is placed between the heated interior and the roof membrane. In winter, insulation temperatures may be below the dew point of the room air for long periods. Condensed moisture can then saturate insulation, wood decks, and roof sheathing; the subsequent soaking of the insulation can damage interior materials.

Wet insulation in level roof construction is difficult to dry. Even with some slope, drainage is likely to be so slow as to be ineffective. Ventilation to the outside is not effective for drying roof insulation, since forces acting to remove the moisture are small. The vents themselves may present a hazard to the insulation by admitting moisture and drifting snow. Also, water leaks can occur where the vent penetrates the roof, unless they are properly installed. Finally, vents may allow chimney action to carry air upward through openings in the deck and through faults in the vapor retarder. Then as air flows to the outside, further moisture is drawn into the roof with the replacement air; this moisture may condense.

A vapor retarder in a conventional flat roof can trap moisture between the roof itself and the roof membrane. The decision of whether to use a vapor retarder depends on interior humidity and climate. The absence of a vapor retarder allows vapor to enter a roof during the heating season, but it also facilitates the removal of moisture in warm weather. This may not be acceptable in buildings with high humidity, where a large accumulation of frost or liquid condensation results in dripping. Where humidities are lower, the roof system may successfully store moisture through the heating season without problems (Baker 1980).

Regular inspection of the membrane and flashings helps prevent water leakage into the roof. Link (1977), Tobiasson *et al.* (1977), and Hedlin (1974) describe how infrared scanners or capacitance meters can help detect wet insulation, which can be removed or possibly dried out.

The top layers in protected membrane or inverted roof systems are not waterproof; therefore, insulation is exposed to rainwater. To remain effective, it must be able to resist moisture penetration. Extruded polystyrene board has been used extensively. Insulation moisture contents commonly ranges up to 4 or 5% by volume.

Some insulations are damaged by freezing and thawing, fracturing cell walls, and allowing water into an otherwise low-permeance material. When free moisture is available, the rate of entry increases rapidly as the temperature gradient increases (Hedlin 1977). Even when insulation is immersed in ponded water, moisture absorption through the edges is less than through the upper and lower surfaces, since the temperature gradient is normal to the roof surface.

Protective measures can reduce moisture gains. Roof slope performs much the same function for protected membrane roofs as it does for conventional ones. Covering the bottom surface of the insulation with a low-permeance layer inhibits moisture entry

there. The upper surface should be open to the atmosphere so that water can evaporate freely. If it is trapped against the upper surface (*e.g.*, by paving stones), sun heating may drive the water into the insulation.

Where a high thermal resistance is required, roofs may combine conventional and protected membrane systems when they may be applied in two separate lifts. The protected membrane system may be applied to existing conventional roofs to increase the thermal resistance, if the roof structure can support the added weight. This addition keeps the insulation below the roof membrane warmer, so that the danger of moisture condensation entering from below is significantly reduced.

Other Considerations

All previously mentioned considerations require special attention in buildings with high, sustained relative humidity levels. To gain flexible and uninterrupted floor spaces, mechanical service shafts are often located outside the perimeter of the occupied area, allowing unrestricted airflow into exterior wall cavities. Potential problems may be further aggravated by duct leakage. In controlled humidity areas, such as operating rooms, the outflow of moisture to surrounding cavities should be reduced by low-permeance surface finishes such as vinyl fabrics or vapor retarder paints. Complex piping and electrical systems may not permit effective control of air and water vapor flow in the plane of the interior surface. Such interferences require careful placement of air and vapor retarders because they can be rendered ineffective by penetrations of mechanical work. Such penetrations should be kept to a minimum.

Past Practice

While previous methods for determining the need for vapor retarders were based on climatic conditions and geographic location, experience has shown that construction practices, workmanship, and conditions of occupancy can be as significant as climatic conditions in determining the need for vapor retarders.

Average winter temperature and its duration affects condensation. Figure 11 shows the United States divided by −20, 0, and 20°F isotherms of winter design temperature. Zone I roughly includes areas with design temperatures of −20°F or colder; Zone II, design temperatures of 0 to −20°F; and Zone III, those at 0°F and warmer. Within each zone, similar degrees of condensation trouble were expected, and similar corrective measures apply.

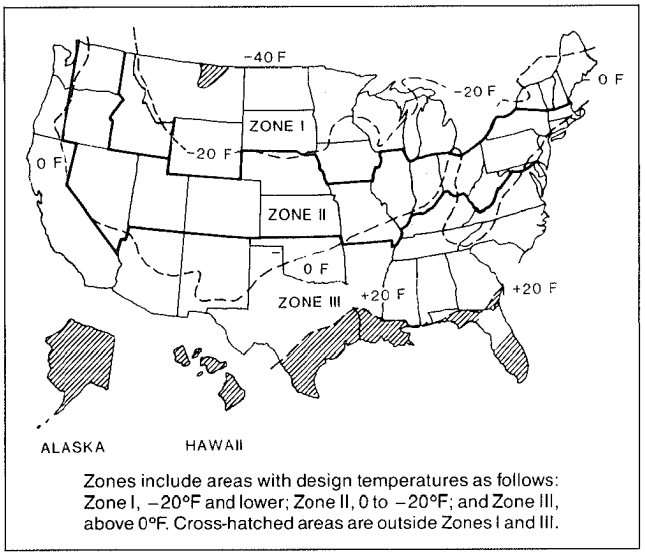
Not all buildings require a vapor retarder, but the walls of every dwelling should include a vapor retarder when it includes any material that would be damaged by moisture through rotting, staining of wall or ceiling surface, freeze-thaw action, or through reduction in the thermal resistance of the envelope system. Vapor retarders should be applied in all three condensation zones when the wall U-factor is less than 0.25 Btu/h·ft²·°F and in Zones I and II, to walls of higher transmittance.

The recommended ventilation shown in Table 1 for dwellings is based on insulated ceilings. The net area refers to the total of all openings free of obstruction. For example, louvers with 8-mesh screen require a gross area 2.25 times that listed. In Zone I (Figure 11), a vapor retarder should be included in all ceilings. Also, openings from walls into the attic or around a loose-fitting attic door must be avoided to keep warm, moist air out.

The Housing Development Directorate (1979) developed Table 2, a checklist for diagnosing moisture-related problems in housing in cold climates.

Crawl Spaces

The *Building Foundation Design Handbook* (Labs *et al.* 1988) notes that ground cover membranes that restrict evaporation of soil moisture are the single most important way to prevent condensation and wood decay problems in crawl spaces. The ground



Zones include areas with design temperatures as follows: Zone I, −20°F and lower; Zone II, 0 to −20°F; and Zone III, above 0°F. Cross-hatched areas are outside Zones I and III.

Fig. 11 Condensation Zones in United States

Table 1 Recommended Practice for Loft and Attic Ventilation

Flat Roof—Slope 3:12 or Less
Condensation Zone I[c]: Total net area of ventilation should be 1/300[b] distributed uniformly at the eaves *plus* a vapor retarder in the top story ceiling. Free circulation must be provided through all spaces.
Condensation Zones II and III: Same as for Zone I.
Gable Roof—Slope 3:12 or More
Condensation Zone I: Total net area of at least 2 louvers on opposite sides located near the ridge to be 1/300[b] *plus* a vapor retarder in the top story ceiling.
Condensation Zone II: Same as for Zone I.
Condensation Zone III: Same ventilation as for Zone II. A vapor retarder is not necessary.
Hip Roof
Condensation Zone I: Total net area of ventilation should be 1/300[b] with 1/600[b] distributed uniformly at the eaves *and* 1/600[b] located at the ridge with all spaces interconnected. A vapor retarder should also be used in the top story ceiling.
Condensation Zone II: Same as for Zone I.
Condensation Zone III: Same ventilation as for Zone II. A vapor retarder is not necessary.
Gable or Hip Roof—With Occupancy Contemplated
Condensation Zone I: Total net area of ventilation should be 1/300[b] with 1/600[b] distributed uniformly at the eaves and 1/600[b] located at the ridge with all spaces interconnected. A vapor retarder should also be used on the warm side of the top full story ceiling, the dwarf walls, the sloping part of the roof, and the attic story ceiling.
Condensation Zone II: Same as for Zone I.
Condensation Zone III: Same as for Zone I, except that a vapor retarder is not necessary if insulation is omitted.

Adapted from *Building Foundation Design Handbook* (Labs *et al.* 1988).

[a]In many areas, increased ventilation may be desirable for summer comfort. For winter comfort, insulation should be placed between a living space and a loft or attic ventilated at these rates.

[b]Refers to area enclosed within building lines at eave level.

[c]The zone numbers refer to Figure 11.

Reprinted from *Condensation and Mould Growth* (Housing Development Directorate 1979).

cover material should have a perm rating of no more than 1.0 and must be rugged enough to withstand foot and knee traffic. Recommended materials include 6-mil (0.006 in.) polyethylene, 45 or 55-lb smooth roll roofing (federal specification Class A, Type 1), and 45-mil (0.045-in.) thick EPDM membranes. Roll roofing should not be used for very wet soils, because fungi will decompose it over time. Any source of subfloor warmth (heating ducts, furnaces) is likely to seriously increase the evaporation from subfloor soil (Trethowen and Middlemass 1988, Trethowen 1988).

All debris must be removed and the soil leveled before laying the membrane. Edges need only be lapped 4 to 6 in., and no sealing is required. The membrane need not be carried up the face of the wall unless the interior grade is below the outside grade.

A rectangular crawl space requires a minimum of four vents, one on each wall, located no farther than 3 ft from each corner. The vents should be as high on the wall as possible to best capture breezes, and landscaping should be planned to prevent obstruction of the vents. The total free (open) area of all vents should be at least 1/1500 of the floor area. The gross area of various vents can be found by multiplying the 1/1500 area by the factors in Table 3. In the absence of a ground cover, the vent area should be increased to 1/150 of the floor area. Ventilation alone should not be relied on where soils are known to be moist.

The most common vent-related failures include: (1) providing 1/1500 in gross vent area instead of free area, (2) placing vents on only one pair of walls or away from the corners, and (3) obstructing the vents by ducts and plumbing, or by shrubbery, condenser units, porches, and patios. Another common problem is the failure of homeowners to open operable vents.

Adequate space under all beams, pipes, and ducts allows access to the crawl space, especially the perimeter. Adequate space also prevents ventilation being impeded. Codes and standard practice usually call for a minimum of 18 in. between the crawl space floor and the underside of joists, but 24 in. is better to leave space for ducts and plumbing.

CONDENSATION IN COOLED STRUCTURES

Refrigerators, cold pipes, and cold vessels require insulation and should have a vapor retarder placed on the warm side of the insulation or as close as possible to the warm surface of any enclosure. Insulation on a cold pipeline has no opportunity to dry out periodically. Also, vapor should not escape from the cold side of any metal (vaportight) pipe. Such applications require insulating materials that are highly resistant to water vapor, or a highly vapor-resistant jacket or coating whose permeance is not over 0.01 perm. Metal coverings are desirable but difficult to apply.

Similar considerations apply in cold rooms, whether constructed inside a heated building or as a separate building. Cold rooms operating above freezing experience some periods of vapor reversal in winter, but such drying is of little help. Refrigerators lined with cement or other vapor-permeable material allow slight amounts of vapor to pass, which reduces the accumulation of moisture that penetrates the retarder. However, an adequate warm side retarder not greater than 0.01 perm should be installed.

Air can infiltrate through gaps in joints, tears in the retarder, or cracks where pipes or similar items penetrate the wall. Opening and closing cold room doors also causes a pumping of air, which can increase the infiltration of the moist air.

Summer cooling for comfort in temperate climates does not usually create serious vapor problems in exterior walls and ceilings. Outdoor dew point, especially peak values, may exceed the design dew-point temperatures in common use, but they seldom exceed 75 °F for any prolonged period. Condensation within exterior walls exposed to an indoor temperature of 75 °F is seldom as serious as winter condensation.

In a study of a wood-sided house in Athens, Georgia, Duff (1956) showed under summer cooling conditions that temperatures were lower outside than inside long enough to prevent moisture buildup from damaging the structure. This condition held true regardless of whether or not a vapor retarder was placed near the inner surface. Masonry or brick-veneered structures with an efficient vapor retarder near inner surfaces do have a moisture buildup under summer cooling conditions, however. Observed moisture contents in wood framing exceeds 25 to 30% by dry weight, which is conducive to wood decay and metal corrosion. Mei and Woolrich (1963) reported summer condensation in exterior walls and crawl spaces in some areas. For this reason, in areas of prolonged heavy cooling and shorter heating seasons, tight vapor retarders are discouraged.

A vapor retarder to prevent condensation within exterior walls under summer cooling conditions would normally be located on the outside of the insulation, whereas under winter conditions, it would be located on the inner side. Use of vapor retarders at both locations can restrict not only the entry of moisture into the insulation but the escape of any moisture as well. In dwelling construction, the vapor retarder should be placed to protect for the more serious case of winter condensation; the summer case should be disregarded, even when some condensation is expected. The corresponding situation in cold storage buildings, in which a more serious reversal of vapor flow conditions from winter to summer may occur, poses a wall design problem not yet fully resolved.

Serious wetting within walls can occur in summer under special conditions. The National Research Council of Canada tested the walls of huts of brick masonry, finished inside with furring, insulation, vapor retarder, and plasterboard interior. The walls were opened during a sunny period following rain. Extensive wetting was observed in the insulation, particularly on the back of the vapor retarder. The absorptive brick wall had taken on substantial quantities of water during the rainfall. Subsequent heating by the sun had driven the moisture as vapor into the wall, where it condensed and caused serious wetting. The construction had no protection in the form of parging or paper on the inside of the brick for the furring and insulation. Walls with absorptive exterior coverings capable of absorbing and storing considerable quantities of water during a rain, and providing little resistance to vapor flow into the insulation from outdoors, may experience serious interior wetting by condensation under these unusual conditions. No wetting occurred in a similar construction when a saturated sheathing paper was used between the insulation and the brick. Thus, a moderate vapor flow resistance, such as that provided by parging or a good sheathing paper on the outside of the insulation, can be effective in such cases.

Vapor that diffuses inward under cooling conditions adds to cooling loads. Vapor retarders installed for winter conditions help reduce this. However, if condensation occurs on the back of a vapor retarder installed on the inside of the insulation, the latent heat released may add to the heat gain through the wall.

Table 3 Crawl Space Vent Area Requirements

Obstructions in Vents	No Soil Cover[a] Multiply Gross Vent Area by[c]	With Soil Cover[b] Multiply Gross Vent Area by[c]
1/4-in. mesh hardware cloth	10	1.0
1/8-in. mesh screen	12.5	1.25
16-mesh insect screen	20	2.0
Louvers + 1/4-in. hardware cloth	20	2.0
Louvers + 1/8-in. mesh screen	22.5	2.25
Louvers + 16-mesh screen	30	3.0

[a]Vent area may be reduced by one-half if the crawl space floor soil is dusty dry.
[b]The indicated amount or four vents, whichever is greater.
[c]As determined by the 1/1500 formula.

AIR-CONDITIONED BUILDINGS IN HUMID CLIMATES

A number of moisture-related problems have been identified in humid and tropical climates (Moore *et al.* 1980). While the principles of moisture flow remain the same, climatic differences present different problems. A humid climate can be defined as one in which one or both of the following conditions occur:

1. A 67 °F or higher wet-bulb temperature for 3500 h or more during the warmest six consecutive months of the year.
2. A 73 °F or higher wet-bulb temperature for 1750 h or more during the warmest six consecutive months of the year.

Figures 12 and 13 show the locations of humid climates satisfying the definition in the United States and the world.

Depending on local experience with moisture problems, a humid-climate design criteria may also be desirable in locations that do not quite meet the foregoing conditions. Fringe areas include some locations in the southeastern United States, notably Alabama, Arkansas, Georgia, Louisiana, Mississippi, North Carolina, South Carolina, and east Texas (see Figure 12). Fringe locations are generally identified by one or both of the following conditions:

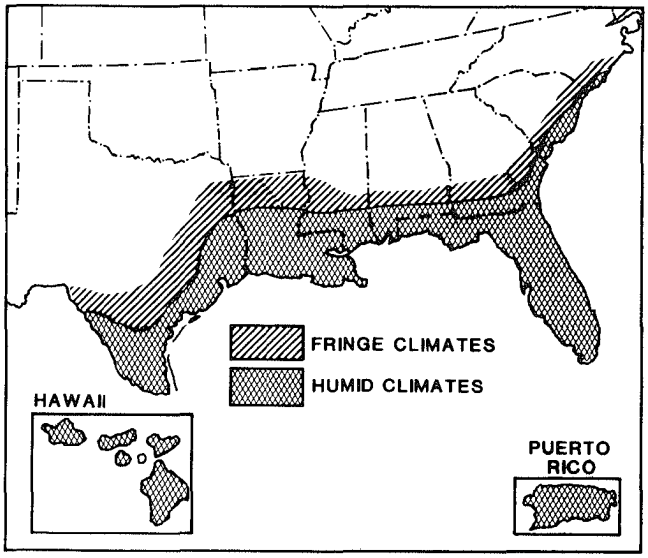

Fig. 12 Humid Climates in Continental United States

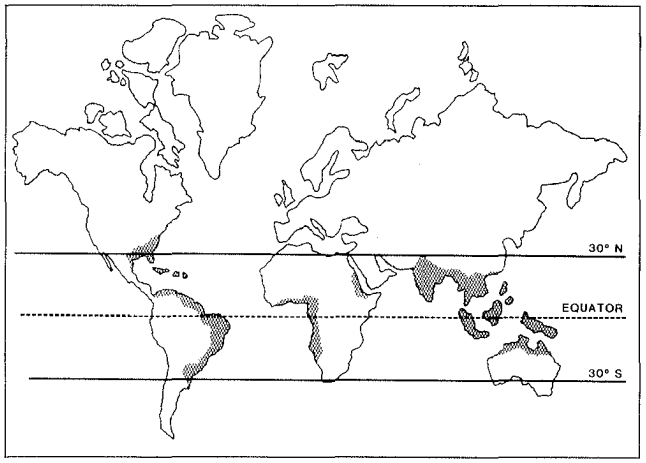

Fig. 13 Humid Climates Generally Occur in Latitudes 30 °S to 30 °N in Low Coastal Regions

1. A 67 °F or higher wet-bulb temperature for 3000 h or more during the warmest six consecutive months of the year.
2. A 73 °F or higher wet-bulb temperature for 1500 h or more during the warmest six consecutive months of the year.

Mold and Mildew

Air-conditioned buildings in humid climates tend to experience growth of mold and mildew which can cause decay of wood. A reliable air-conditioning system with good humidity control will decrease indoor humidity and provide adequate air circulation to reduce indoor mold and mildew.

Design Practices

In high humidity climates, the outdoor to indoor vapor pressure differential can be twice as much as in humidified buildings in cold climates. Thus, the moisture load caused by diffusion through the building envelope may need to be considered, even though the calculation is imprecise. This load is in addition to ventilation, infiltration, and internally generated moisture loads.

Since the latent cooling load on an air-conditioning system in high humidity climates frequently exceeds the sensible load, a system should be capable of handling the latent load without overcooling. Oversized air-conditioning units contribute to the problem of high humidity, since the latent capacity drops off faster than does the sensible capacity.

The most successful approach to solving this problem includes proper sizing of the air-conditioning system and use of reheat. An air-conditioning system capable of operation at a low sensible heat ratio and with multiple capacities may suffice in some cases. The air-conditioning systems commonly used in other climates, *i.e.*, those with limited dehumidification capability, especially under light sensible loads (such as room fan coil units handling the full load), should be avoided. Any air-conditioning system capable of providing comfort conditions within the range shown in the ASHRAE Comfort Standard Chart (Chapter 8), under all sensible loads, will prevent the growth of mold and mildew indoors. All-air systems with reheat generally provide satisfactory conditions.

Ventilating air should be continuously dehumidified since its vapor pressure is usually higher than that of indoor air. Similarly, infiltration should be minimized. Temperature controls for air-conditioning units, especially those handling outside air, should not allow variable temperature supply air unless humidity is also controlled. When the control system permits supply air temperature to increase with a consequent reduction in dehumidification, previously cooled surfaces (such as ceilings, diffusers, or registers) may be at temperatures below the dew point of the supply air, causing condensation.

Unconditioned or unventilated spaces in an air-conditioned building should be conditioned or connected by openings to conditioned spaces to prevent the possibility of mold growth.

In high humidity climates, moisture condenses on the exterior surface of a building because its temperature is frequently lower than the ambient dew point. In roof systems with high relative humidity under the roof, condensation may occur at night on the bottom surface of the roofing, wetting the insulation. This may be mistaken as a leaking roof, even though it may not have rained for days.

If condensation is not reevaporated by wind or solar heat gain, it can be reduced by (1) using higher thermal resistances in the building envelope to raise exterior surface temperatures and (2) avoiding shaded exterior surfaces that do not benefit from the evaporative effects of sun and wind, such as inside corners. Special attention should be focused on building components that have thermal bridges, such as exterior cantilevers, columns, foundations, or window and door frames. While these solutions may not totally eliminate mold and mildew growth, they substantially reduce the potential.

Water vapor diffuses through building materials from the outside into air-conditioned spaces in high humidity climates. Exterior surfaces should have higher vapor resistance than interior surfaces in such climates. Paints and finishes can provide the necessary vapor resistances, with the greater vapor resistance at the outside surface and lower vapor resistances toward the inside.

Where vapor retarders are used, they should be on the outside. Therefore, any water that does enter the construction can flow through to the inside of the building where it can be removed by the air-conditioning system instead of accumulating in the wall or roof construction. Note that this is the reverse of the recommended practice for cold climates.

Insulated cold piping (and sometimes ductwork) should receive special attention when exposed to ambient or nonconditioned air. Because cold piping frequently operates year-round, a constant vapor drive will exist under humid conditions. Even with vapor retarder insulation, jackets, and vapor sealing of joints and fittings, moisture inevitably accumulates in permeable insulations. This moisture not only reduces the thermal resistance of the insulation, it also accelerates condensation on the jacket surface with consequent dripping of water and growth of mold and mildew. Depending on local conditions, these problems can arise in less than 3 years, or they can take as long as 20 or 30 years. Since periodic insulation replacement is the only known solution, the piping installation should be accessible for such replacement and should have a means for draining water. As an alternative, very low permeance-type insulating materials (for example, materials not exceeding 0.1 perms) have been used to extend the life of the system and reduce replacement frequency. The lower the permeance of the insulation material, the longer its life.

Operating and Maintenance Practices

Since the potential for damage to a building and its contents is substantial in an air-conditioned building in humid climates, it is more important to properly operate and maintain the building and its air-conditioning system in humid climates than it is in others. The chilled water supply temperature and flow should be reliable, and multiple chillers and pumps should be considered to assure continuous uninterrupted dehumidification. Raising the chilled water supply temperature to conserve energy should not be attempted under these conditions.

INDUSTRIAL INSULATION PRACTICE

The applications of industrial insulation discussed in this section include: (1) pipes; (2) tanks, vessels, and equipment; (3) ducts; and (4) refrigerated rooms and buildings.

PIPES

Small pipes are insulated with cylindrical half-sections of insulation, with factory-applied jackets that form a hinge-and-lap, or with flexible, closed-cell material. Large pipes can be insulated with flexible material or with curved, flat segmented, or cylindrical half-, third-, or quarter-sections of rigid insulation, particularly where removal for frequent servicing of the pipe is necessary. Fittings (valves, tees, crosses, and elbows) are insulated with preformed fitting insulation, fabricated fitting insulation, individual pieces cut from sectional straight pipe insulation, or insulating cements. Fittings insulation should always be consistent with pipe insulation.

Securing Methods

The method of securement varies with the size of pipe, form, and weight of the insulation, and the type of jacketing, *i.e.*, separate or factory-applied. Insulation with certain factory-applied jacketing can be secured on small piping by cementing the overlapping jacket. Large piping may require supplemental wiring or banding. Insulation on large piping requiring separate jacketing is wired or banded in place, and the jacket is cemented, wired, or banded, depending on the type. Insulation with factory-applied metal jacketing is secured by specific design of the jacket and its joint closure. The flexible closed-cell materials require no jacket for most applications, and they are applied using specially formulated contact adhesives.

Insulation Finish for Above-Ambient Temperatures

Pipe insulation finishes for indoor use are usually governed by location. If concealed, the simplest finish is a laminate of kraft paper, glass fiber reinforcing, and a vapor retarder. If exposed, the finishes are factory-applied jackets designed to meet fire safety requirements. For maximum fire safety, unusual exposure conditions, or appearance, factory or separately applied metal jackets may be used. Flexible closed-cell material usually is painted where exposed and left unfinished where hidden. An outdoor finish protects the insulation from the weather; chemical exposure, mechanical abuse, and appearance are additional considerations.

Insulation Finish for Below-Ambient Temperatures

Piping at temperatures below ambient is insulated to control heat gain and prevent condensation of moisture from the ambient air. Since piping is an absolute barrier to the passage of water vapor, the outer surface of the insulation must be covered by an impervious membrane or cover, which also helps protect the pipe against corrosion.

Retarder treatment should be recommended by the insulation manufacturer as established by performance testing. To protect the insulation from undue weather exposure, it must be as dry as possible.

Vapor-seal finishes for straight pipe insulation are generally designed to meet operating temperature, fire safety, and appearance requirements. Jacketing commonly consists of various combinations of laminates of paper, aluminum foil, plastic film, and glass fiber reinforcing. An important feature of such jacketing is very low permeance in a relatively thin layer, which provides flexibility for ease of cementing and sealing laps and end-joint strips. This type of jacketing is commonly used indoors without additional treatment. In some cases of subzero operating temperature, multilayer insulation and jacketing may be used. Flexible closed-cell materials must be carefully cemented to avoid openings in the insulations.

Insulation fittings are usually vapor-sealed by field applications of suitable materials and may vary with the type of insulation and operating temperature. For temperatures not below 10 °F, the vapor seal can be a lapped spiral wrap of plastic film adhesive tape or a relatively thin coat of vapor-seal mastic. For temperatures below 10 °F, common practice is two coats of vapor-seal mastic reinforced with open-weave glass or other fabric. The thickness of the mastic increases with decreasing temperature. With long lines of piping, the insulation should be sealed off every 15 or 20 ft to limit water penetration if vapor-seal damage occurs.

For dual-temperature service, where piping is alternately cold and hot, the vapor-seal finish, including mastics, must withstand pipe movement and exposure temperatures without deterioration. When flexible closed-cell insulation is used, it should be applied slightly compressed to prevent it from being strained when the piping expands.

Outdoor pipe insulation may be vapor-sealed in the same manner as indoor piping, by applying added weather protection jacketing without damage to the retarder and sealing it to keep out water. In some instances, heavy-duty weather and vapor-seal finish may be used. Table 4 shows the minimum spacing allowed to permit proper application and sealing of pipe insulation.

Table 4 Estimated Requirements to Prevent Freezing of Water in Pipes[a]

Nominal Pipe Size, in.	Time to Cool Water to Freezing, h[b]			Water Mass Flow Rate per Unit Length of Exposed Pipe to Prevent Freezing, lb/(h·ft)[b]		
	Insulation Thickness, in.[c]					
	2	3	4	2	3	4

[a]Surrounding air temperature = −18°F.
[b]Initial water temperature = 42°F.
[c]Insulation thermal conductivity = 0.30 Btu·in/h·ft²·°F.

Surface Temperature

In elevated temperature applications, the surface temperature of the insulation system should be below that at which personnel coming into contact with the surface could be harmed. In below-ambient temperature applications, the surface temperature of the system should be above dew point to prevent condensation.

A jacket with a reflective surface will have a higher surface temperature for hot applications than for cold temperature applications because the lower emissivity reduces the rate of heat exchange. Therefore, adding a reflective jacket could produce a surface temperature capable of burning personnel on hot applications and causing condensation on cold applications. The jacketing material used also contributes to the relative safety at a given surface temperature. For example, at 175°F, a stainless steel jacket blisters skin more severely than a canvas jacket does. Consult Chapter 22 for surface temperature calculation procedures and surface resistances at several emittance levels.

Insulating Pipes to Prevent Freezing

If the surrounding air temperature remains sufficiently low for an extended period, insulation cannot prevent freezing of still water or of water flowing at a rate insufficient for the available heat content to offset the heat loss. Insulation can only prolong the time required for water to freeze and prevent freezing if water flow is maintained at a sufficient rate; the first section can be used to estimate the thickness of insulation necessary to prevent freezing of still water in pipes; the second section gives the minimum flow of water at an initial temperature of 42°F to prevent the temperature of the pipe from reaching 32°F at the end of the exposed length.

To calculate time required, the following equation can be used:

$$H = B_f (t_i - t_f)/q_o \, (\pi r_2/6) \tag{1}$$

with

$$q_o = k \frac{0.5(t_1 + t_f) - t_2}{r_2 \ln (r_2/r_1)} \tag{2}$$

where

B_f = heat content of water, Btu/lb·°F
= $(\pi r_i^2/a)bc_p$
c_p = specific heat of water, Btu/lb·°F
a = 144 in²/ft²
b = 62.4 lb/ft²
θ = time for water to cool to freezing temperature, h
q_o = heat flow from outer surface of insulation, Btu/h·ft²
r_i = inside radius of pipe, in.
r_1 = outer radius of pipe or inner radius of insulation, in.
r_2 = outer radius of insulation, in.
k = thermal conductivity of insulation, Btu in/h·ft²·°F
t_1 = initial water temperature, °F
t_2 = temperature of outer surface of insulation, °F
t_f = freezing temperature, °F

Refer to Chapter 33 or manufacturers' catalogs and handbooks for pipe capacities.

To calculate water flow, the following equation can be used:

$$W/L = 1/[R_T \ln (O_i/O_o)] \tag{3}$$

where

W = flow rate required to keep pipe free of ice, lb/h
L = length of exposed pipe, ft
R_T = $R_I + R_f$ = total resistance to heat flow between water and ambient air per foot of pipe
R_I = $[\ln (D_I/D_p)]/(2\pi K_I)$ = resistance of thermal insulation per foot of pipe, ft·°F·h/Btu
R_f = $1/(\pi K_W \text{Nu})$ = resistance between water and inner surface of pipe per foot of pipe = 0.23 ft·°F·h/Btu
O_i = $t_i - t_a$, difference between initial water temperature and ambient air temperature, °F
O_o = $(R_T/R_I)(t_f - t_a)$
t_a = ambient air temperature, °F
D_I = outside diameter of insulation, ft
D_p = outside diameter of pipe, ft
K_I = thermal conductivity of insulation, Btu/h·ft·°F
K_W = thermal conductivity of water near freezing
= 0.32 Btu/h·ft·°F
Nu = Nusselt number, a constant value of 4.36 for fully developed laminar flow and constant heat flux

When unusual conditions make it impractical to maintain protection with insulation alone, a hot trace pipe or, preferably, electric resistance heating cable is required along the bottom or top of the water pipe. The heating system then supplies the heat lost through the insulation. The insulation thickness is determined by the cost of the heating system, the insulation, and the heat loss.

Underground Pipe Insulation

Both heated and cooled underground piping systems are insulated. Protecting underground insulated piping is more difficult than protecting aboveground piping. Groundwater conditions, including chemical or electrolytic contributions by the soil and the existence of a water pressure, require a special design to protect insulated pipes from corrosion. Walk-through tunnels, conduits, or integral protective coverings are generally provided to protect the pipe and insulation from water. Examples and general design features of conduits and a description of tunnels can be found in Chapter 11 of the 1992 ASHRAE *Handbook—Systems and Equipment*.

Temperatures above ambient. Piping for heated systems in walk-through tunnels is usually covered with sectional insulation and finished with effective mechanical protection such as metal or waterproofing jackets. The use of walk-through tunnels is declining because of cost.

Conduit systems are generally used for underground insulated piping systems. The most successful application is the use of sectional insulation with the conduit sized for drainage and adequate drying of insulation on heated piping in the event of accidental flooding. BRAB Technical Report 66 (1975) gives detailed design criteria for conduit systems. The criteria require that (1) all systems

provide for draining and insulation drying, (2) the insulation withstand boiling and drying without physical damage and loss of insulating value, and (3) the conduit casing be watertight in the field. The insulation should be a nonconductor of electricity, vermin-proof, and chemically and dimensionally stable at the operating temperature of the pipe.

BRAB Technical Report 39 (1963) describes suitable laboratory tests for compliance with the criteria just discussed. BRAB Technical Report 47 (1964) describes evaluative tests and field investigations which have shown that calcium silicate is resistant to severe boiling action. Fibrous glass (4 to 7 lb/ft^3 density) will not withstand boiling when a conduit becomes flooded, and wet poured-in-place insulations are likely to remain partially wet for their installed life.

The thickness of insulation for underground piping is not determined on the same basis as aboveground piping.

Temperatures below ambient. Integrally protected, insulated piping buried directly in the ground is commonly used for chilled water. However, since no heat is available to drive out moisture, an absolute protective covering against water and insulation with low permeance and water absorption is extremely important. Cellular glass with proper protection has been widely used for this type of application. The acceptance of plastic foams is increasing, but their long-term performance has not yet been established.

Conduit for chilled water piping requires a different approach than for hot piping. Insulation must have low conductivity, and conduit design must use this low conductivity and maintain continuing performance. More recent designs use low-conductivity plastic foam insulation with plastic pipe as the internal water-carrying piping and as the external conduit.

Where the temperature difference between the pipe at 40 °F and the soil at 55 to 60 °F is small, pipe size, length, and flow rate may economically justify direct burial without insulation. However, good piping protection may be required.

TANKS, VESSELS, AND EQUIPMENT

Flat, curved, and irregular surfaces, such as tanks, vessels, boilers, and chimney connectors, are normally insulated with flat blocks or bevelled lags, curved segments, blanket forms of insulation, or mineral fiber-inorganic binder insulations. On surfaces operating below 185 °F, closed cellular insulations are used extensively. Since no general procedure can apply to all materials and conditions, manufacturers' specifications and instructions must be followed for specific applications.

Securing Methods

Insulations are secured in a variety of ways, depending on the form of insulation and contour of the surface to be insulated. On small-diameter, cylindrical vessels, insulation can be secured by banding around the circumference. On larger cylindrical vessels, banding can be supplemented by angle iron support ledges to support the insulation against slippage. Where diameters exceed 10 to 15 ft, slotted angle iron may be run lengthwise on the cylinder, at intervals around the circumference, as securement, and to avoid an excessive length of banding.

On large flat and cylindrical surfaces, banding or wiring can be supplemented by fastening to various welded studs at frequent intervals. On large flat, cylindrical, and spherical surfaces, it is often advantageous to secure the insulation by impaling it on welded studs or pins and fastening it with speed washers. Flexible closed-cell insulations are adhered directly to the surface to be insulated, using a suitable contact adhesive.

Insulation Finish for Above-Ambient Temperatures

For temperatures above ambient, insulation is finished to protect it against mechanical damage and weather, consistent with acceptable appearance. On smaller equipment indoors, insulation is commonly covered with hexagonal wire mesh tightly stretched and secured. Then a base and hard finish coat of cement is applied. This can be additionally finished by painting.

For the same equipment outdoors, the insulation can be finished with a coat of hard cement, hexagonal mesh properly secured, and a coat of weather-resistant mastic (preferably a breathing type). A variation is to apply only two coats of weather-resistant mastic reinforced with open-mesh glass or other fabric; but this finish is limited to about 300 °F operating temperature, as metal expansion can rupture the finish at insulation joints. Larger equipment may be finished indoors and out with suitable sheet metal. Outdoor finish of any type must be properly flashed around penetrations (*e.g.*, manhole access openings, pipe connections, and structural supports) to maintain a weatherproof condition.

Insulation Finish for Below-Ambient Temperatures

For temperatures below ambient, insulation is finished, as required, to prevent condensation and protect against mechanical damage and weather, consistent with acceptable appearance. In accordance with the operating temperature, the finish must retard vapor to avoid moisture entry from surrounding air, which can cause an increase in thermal conductivity of the insulation, deterioration of the insulation, or corrosion of the metal equipment surface. For moderately low temperatures, insulation can be finished with hexagonal mesh properly secured, a coat of hard finish cement, and several coats of suitable paint. Where a greater degree of vapor retarding is required, two coats of mastic reinforced with open-mesh glass or other fabric can be used. For an even greater degree of vapor retarding, two coats of asphalt vapor-retarder mastic reinforced with asphalt-saturated and perforated felt with edges lapped and cemented can be used (see Table 9, Chapter 22). If this type of vapor retarding is used indoors, standards for acceptable appearance and protection from mechanical damage may require the addition of hexagonal mesh, hard finish cement, and finish painting.

For the same equipment outdoors, the insulation can be finished with heavier or additional coats of vapor-retarder mastic reinforced with open-mesh glass or other fabric. For appearance, mastics can be painted, but since they usually contain solvents, they must be properly dried before painting. Paints must be the appropriate type recommended by paint manufacturers. In some cases, the additional finish over the mastic may be suitable sheet metal, applied carefully so as not to damage the vapor retarder (see Table 9, Chapter 22 for material properties).

Whenever vapor retarder finish is applied, all penetrations such as manholes, pipe connections, and structural supports must be properly vapor retarded with mastic or other sealant reinforced with open-mesh glass or other fabric. Equipment must be insulated from structural steel by isolating supports of high compressive strength and reasonably low thermal conductivity, such as hardwood block. The vapor retarding must carry over this insulation from the equipment to the supporting steel to assure proper sealing. If the equipment rests directly on steel supports, the supports must be insulated for some distance from the points of contact. Commonly, insulation and vapor retarder are extended 8 to 10 times the thickness of the insulation applied to the equipment.

For dual-temperature service, where vessels are alternately cold and hot, the materials and a design of vapor retarder finish selected must withstand movement caused by temperature change.

Reflective insulation is commonly applied to large refrigerated tanks. In this system, the external finishing sheets of heavy-gage metal form the vapor retarder, and the joints are sealed to permit contraction and expansion. Valved outlets at the bottom of the tank allow drainage.

DUCTS

The need for duct insulation is influenced by (1) duct location, whether indoors or outdoors; (2) the effect of heat loss or gain on equipment size and operating cost; (3) the need to prevent condensation on low-temperature ducts; (4) the need to control temperature change in long duct lengths; and (5) the need to control noise with interior duct lining.

All ducts exposed to outdoor conditions, as well as those passing through unconditioned spaces, should be insulated. While analyses of temperature change, heat loss or gain, and other factors affecting the economics of thermal insulation are seldom made for residential installations, they are essential for large commercial and industrial projects.

The U-value for uninsulated sheet metal ducts is affected by air velocity, the emittance of the metal, and the shape of the duct. An approximate value of 1.0 Btu/h·ft²·°F may be used. For insulated ducts, U-factors of 0.24 and 0.13 Btu/h·ft²·°F represent 1- and 2-in. thick rigid insulation with a thermal conductivity of 0.27 Btu·in/h·ft²·°F at 75°F mean temperature. A method for determining heat loss or gain for ducts is given in Chapter 32.

Materials for Ducts, Insulations, and Liners

Ducts within buildings can be of insulated sheet metal or fibrous glass, both of which provide combined air barrier, thermal insulation, and sound absorption. Ducts embedding in or below floor slabs may be of compressed fiber, ceramic tile, or other rigid materials.

Duct insulations include semirigid boards and flexible blanket types, composed of organic and inorganic materials in fibrous, cellular, or bonded particle forms. Insulations for exterior surfaces may have attached vapor barriers or facings, or vapor barriers may be applied separately. When applied to the duct interior as a liner, insulation both thermally insulates and absorbs sound. Duct liner insulations have sound-permeable coatings or other treatment on the side facing the airstream to withstand air velocities without deterioration.

Fibrous glass ducts are available in preformed round ducts or in board form for fabrication of rectangular ductwork. Round and rectangular ducts have a minimum density of about 3 lb/ft³, with a thermal conductivity of 0.23 Btu in/h·ft²·°F at 75°F mean temperature. Round ducts with a diameter of up to about 30 in. and boards in various thicknesses and sizes are used to form required sizes of rectangular ducts. Maximum recommended velocity is 2000 fpm, although tests at velocities exceeding 10,000 fpm show no fiber erosion. Primary use is for low-pressure systems tested at 1.5 times the recommended static pressure. Maximum recommended air temperature is 250°F. A complete system provides greater decibel attenuation than is usually provided by standard duct liners, with greater reduction in airborne equipment noise and crosstalk. Higher design velocities are also possible.

To satisfy most building codes, the various duct insulations and fibrous glass duct materials must meet the fire hazard requirements of the National Fire Protection Association's *Standard* 90A (NFPA 1989), to restrict spread of smoke, heat, and fire through duct systems, and to minimize ignition sources; and *Standard* 90B (NFPA 1989), on supply ducts, controls, clearances, heating panels, return ducts, air filters, and heat pumps. Local code authorities should also be consulted.

Where thermally insulated air-conditioning ducts pass through unconditioned spaces, such as attics, the maximum allowable heat flux should be no greater than that required by NFPA *Standard* 90A.

Securing Methods

Exterior duct insulation can be attached with adhesive, with supplemental preattached pins and clips, or with wiring or banding. Liners can be attached with adhesive and supplemental pins and clips.

Manufacturers provide information on the construction of fibrous glass duct systems. Preformed round duct for straight runs is combined with fittings fabricated from straight duct. Rectangular ducts and fittings are fabricated by grooving, folding, and taping, with metal accessories such as turning vanes, splitters, and dampers incorporated into the system. When rectangular ducts exceed predetermined dimensions for particular static pressures, ductwork must be reinforced. The Sheet Metal and Air Conditioning Contractors National Association's (SMACNA) *Fibrous Glass Duct Construction Standards* has further information.

Heating Ducts

The effect of duct insulation on residential heating system equipment size can be marginal. However, insulation can reduce operating costs significantly, depending on unit costs for heating and the extent of duct exposed to outside conditions. In addition, duct insulation maintains the supply air temperature, which may keep the entering air within a more comfortable range when it enters the conditioned space.

Vapor retarders are not required on exterior insulation of ducts used for heating alone, but they must be provided for ducts used for alternate heating and cooling.

Cooling Ducts

Insulation can reduce operating costs and cooling equipment size significantly. The advantage of adequate insulation is especially significant in areas with high dry-bulb and dew-point temperatures. Ducts for summer air conditioning are insulated with the same materials as heating ducts. Ducts in any unconditioned space should be insulated and have vapor retarders to prevent condensation. Joints and laps in the vapor retarder must be sealed. Flexible closed-cell insulation does not always need a supplemental vapor retarder, but care must be taken to form vapor-tight seams at joints.

REFRIGERATED ROOMS AND BUILDINGS

Cold storage facilities require the most attention to thermal insulation and air/vapor retarders, since they greatly influence costs. Many refrigerated spaces operate at subzero temperatures (as much as 100°F below outside temperature), which increases the severity of the service condition imposed on the insulation system. The primary source of moisture is airborne water vapor; however, soil moisture must also be considered because whenever moisture freezes (either in the insulation system or in soil under slabs-on-ground), both operating and maintenance costs increase. Control of moisture entry into the insulation is of primary importance in limiting water and ice collection in the structure. The location and integrity of the vapor retarder system is crucial and places a premium on good workmanship.

Interior Finish

The permeance of the interior finish, *e.g.*, paint, should be greater than that of the vapor retarder so that the drywall, etc., can dry out to the direction of the finish and away from the vapor retarder.

The panels in structural panel systems fill in between structural members and, therefore, become the building surfaces. Where panels are used as a building lining, no special surface preparation is needed, assuming the surfaces are sound and reasonably smooth. Sheet metal and other specialty boards (when installed to permit passage of water vapor, if necessary) have been successfully used for walls and ceilings of rooms operating over a wide temperature range.

Table 5 Recommended R-Values for Refrigerated Facilities

Facility	Temperature Range, °F	Recommended R-Values, °F · ft² · h/Btu[a] Floors	Walls/ Suspended Ceilings	Roofs
Cooler	40 to 50	Perimeter insulation only	17 to 30	25 to 35
Chill cooler[b]	28 to 35	15 to 20	25 to 35	30 to 40
Holding freezer	−10 to −20	30 to 35	33 to 50	40 to 50
Blast freezer[c]	−40	35 to 40	50 to 60	50 to 60 (Suspended ceilings)

[a]The above R-values were derived using the economic thickness methods previously described in this chapter. Due to the wide range in the cost of energy and insulation materials on a thermal performance basis, a recommended R-value is a guide. For more exact values, consult a designer, insulation supplier, or both.
[b]If a cooler has the possibility of being converted to a freezer, the owner should consider insulating the facility with the higher R-values from the freezer section.
[c]R-values shown are for a blast freezer built within an unconditioned space. If built within a cooler or freezer, consult a designer and/or insulation supplier.

Insulated structural panels, with metal exteriors and metal or reinforced plastic interior faces, are commonly used for cooler and freezer rooms. These finishes keep moisture out of the insulation, so that only the joints between panels must be vapor-sealed to avoid moisture penetration.

In selecting an interior finish, the following factors should be considered: (1) fire resistance, (2) washdown requirements, (3) mechanical damage, (4) moisture and gas permeance, and (5) applicable codes in food-handling installations. All interior walls of insulated spaces should be protected by bumper guards and curbs whenever there is possibility of damage to the finish.

Thermal Resistance

Generally, the R-values in Table 5 may be used for the different types of facilities noted. The range in R-values results from variation in cost of energy, insulation materials, and climatic conditions. For more exact values, consult a designer and/or insulation supplier. R-values less than those shown should not be used.

LAND TRANSPORT VEHICLES

Insulation installed in transport vehicles should have the same qualities desirable for most other applications, *i.e.*, moderate cost, low density, low thermal conductivity, low moisture permeability and retention, ease of application, uniformity, resistance to breakdown at temperature extremes, and fire resistance. The insulation should resist cracking, crumbing, shifting, and pack-down from shock, vibration, and flexing of the body structure that occurs in transport.

State laws and other factors limit the outside width, height, and length of vehicles. Therefore, the designer must establish an insulation thickness to obtain the optimum cargo space and operating performance. For example, increasing insulation thickness from 3 to 4 in. in a 40-ft long highway trailer decreases cargo space by about 100 ft³, or 5%. A decrease in insulation thickness, assuming other factors remain equal, requires an increase in refrigerating or heating unit capacity. In determining the optimum thickness of insulation, the vehicle body and its refrigeration or heating unit must be considered as one system.

Urethane foam insulations are used increasingly for transport vehicles, although glass fiber, polystyrene, and other materials continue to be used. Urethane can be formed in place between the inner and outer skin of the vehicle, or it can be preformed outside the vehicle.

The total amount of heat transferred from outside to inside a vehicle, excluding heat that enters when the vehicle door is open for loading or unloading of cargo, is composed of (1) heat transferred through insulation, (2) heat transferred through structural members, and (3) heat caused by air and moisture leakage into the vehicle and insulated space.

Since air leakage can significantly affect the overall heat transfer rate of the vehicle body, some buyers specify a maximum rate of air leakage that the body can have with a given air pressure imposed in the cargo space. Further, the buyer often specifies the maximum overall heat transfer rate for the vehicle, usually at conditions of 100 °F and 50% rh outside and 0 °F inside air temperature. Chapters 28 and 29 of the 1990 ASHRAE *Handbook—Refrigeration* have further information on refrigerated land transport vehicles.

ENVIRONMENTAL SPACES

Atmospheric environmental spaces provide environments of selected temperature, humidity, pressure, and composition. These may be desired singly or in combination, in stabilized degree or in phased fluctuating degree. The designed environment may be required for short- or long-term tests, for continued or periodic production or manufacture, or for short- or long-term storage. Design requirements and specifications for vapor retarder construction, thermal insulation construction, and protective finish of insulation construction should include performance requirements in terms of (1) permissible water vapor permeance; (2) thermal transfer; and (3) physical and structural requirements for protective finish based on environmental conditions, range of temperature exposure, and permeance to water vapor or other gases to which it may be exposed or for which it may be a controlling boundary.

In a tightly designed system, pressure changes caused by temperature change alone can be sufficient to rupture the insulation system. The effect of vacuum during a pulldown can also tear a barrier fastening.

The manufacture of electronic equipment; pharmaceutical and biological chemicals; textiles, paper, and tobaccos; and packing facilities for such items as critical electrical cable, requires refrigeration equipment to maintain the proper environment. The permissible water vapor permeance rates through walls, ceilings, and floors of the manufacturing space must be considered in the design load calculations for humidification equipment.

Controlled atmosphere storages for fruit and other perishable commodities are held at refrigerated temperatures and control the percentage of oxygen, carbon dioxide, and other gases in the air mixture within the space. Permeance of these gases through the internal gas barrier, which is normally also the protective finish of the thermal insulation, as well as the water vapor permeance through the external water vapor retarder, which should not exceed that of the internal gas barrier, should be specified.

General Principles

The insulation principles for refrigerated rooms or buildings given in this chapter apply only to steady-state operation. Environmental facilities used for alternate refrigerated and high temperatures are subjected to reversal of vapor flow and are usually designed with vapor retarders of equal permeance on both sides of the thermal insulation.

In altitude chambers, heavy welded steel shells form an external structure that resists the pressure differences between external atmospheric and internal vacuum conditions.

Environmental conditions at normal ambient temperatures and above, with injected high humidity, present problems of operation similar to those described for tanks and vessels. Interior protec-

tive finish on thermal insulation is usually designed with the lowest possible water vapor permeance through the protective material and its sealed joints, or with some provision for draining condensate that can be expected in the thermal insulation construction.

Altitude chambers with prestressed shells are generally designed with the insulation on the inside of the shell. This protects the shell from extremes of temperature and eliminates the effect of the shell's thermal mass on the refrigeration load during a rapid pulldown of temperature.

The insulation design must also consider the heat transfer through sleeves, pipes, conduits, door jambs, observation windows, and other openings, but a general guide to insulation thickness for low temperatures is:

$$x = 0.15k\,(t_o - t_i) \tag{4}$$

where

x = insulation thickness, in.
k = conductivity of insulation, Btu·in/h·ft²·°F
t_o = design ambient temperature, °F
t_i = chamber temperature, °F

The use of Equation (4) results in an outside surface temperature of less than 5 °F below ambient.

When the temperature-controlled space involves both heating and refrigeration, the thermal resistance of the structure should be designed to satisfy the most severe need. Thermal insulation should be selected to perform safely at all the temperatures encountered. The effect of thermal mass of insulation and protective finish and the temperature change rate should also be considered.

The thermal insulation construction must prevent the insulation material from (1) settling with ensuing noninsulated voids, (2) deteriorating through thermal shock, and (3) absorbing or retaining flammable liquids or vapors (if present in the environment of the space).

General Installation Technique

The four types of insulation described in this chapter (rigid, loose-fill, flexible, and reflective) can be used in environmental space insulation construction. Requirements of vapor control, temperature range, thermal mass, and effect on temperature pulldown rate are set by the specification of environmental conditions.

Reflective insulations in the form of aluminum alloy sheets with emittances of 0.05 to 0.03, spaced to form the requisite number of dimensioned air spaces, are used extensively in large altitude chambers, low-temperature test rooms, and large all-weather rooms. The inherent low thermal mass of this insulation construction is advantageous for rapid temperature pulldown. Evacuation of air in spaces between reflective insulation sheets must be simultaneous with evacuation of air from the environmental space, either by vent openings through the protective liner of the thermal insulation, or by bleed lines exhausting the thermal areas to the main evacuation line. Bleed lines permit the use of a completely sealed protective liner between the insulation space and the environmental space, with no pressure differential created against the liner. Drainage of the spaces between reflective insulation sheets is also provided. Resistance to fire is afforded by the limited supply of oxygen in the spaces between the reflective insulation sheets.

Wood separator strips between reflective insulation sheets can be employed from the low range of temperature up to 200 °F. For temperature ranges of 250 to 700 °F, aluminum rods may be used as separators. For temperatures ranging from 700 °F to the limits of stainless steel, a separator system of stainless steel rods and reflective insulation sheets of stainless steel may be used. The protective liner can be heavy-gage aluminum or stainless steel, depending on environmental conditions and temperatures.

Rigid cellular glass insulation can be used in combination with reflective insulation. Use cellular glass in the outer layer of thermal insulation where it does not affect rapid temperature pulldown; use reflective insulation in the inner layer where low thermal mass permits rapid temperature pulldown.

Cellular-glass rigid insulation can be used through a range of high temperatures. It is applied with adhesive or mechanical fasteners and joint sealers designed for the temperatures encountered. The protective finish must be suitable for the same temperatures. The high load-bearing value of cellular-glass permits support of floor constructions. Because the material has low conductivity, it is used to insulate piping in reflective insulation construction.

Mineral fiber insulation in flexible form, often used in reach-in and walk-in altitude chambers and low-temperature test facilities, is manufactured in plants and shipped assembled or in sections.

Organic rigid, foamed plastic rigid, semirigid, flexible, and loose-fill insulation, employed in the temperature range permitted by their physical characteristics, must be designed to preclude contraction cracks, settlement, and condensed water vapor collection.

CHAPTER 22

THERMAL AND WATER VAPOR TRANSMISSION DATA

Building Envelopes 22.1
Calculating Overall Thermal Resistances 22.3
Mechanical and Industrial Systems 22.17
Calculating Heat Flow for Buried Pipelines 22.19

THIS chapter presents thermal and water vapor transmission data based on steady-state or equilibrium conditions. Chapter 3 covers heat transfer under transient or changing temperature conditions. Chapter 20 discusses selection of insulation materials and procedures for determining overall thermal resistances by simplified methods.

BUILDING ENVELOPES

Thermal Transmission Data for Building Components

The steady-state thermal resistances (R-values) of building components (walls, floors, windows, roof systems, etc.) can be calculated from the thermal properties of the materials in the component; or the heat flow through the assembled component can be measured directly with laboratory equipment such as the guarded hot box (ASTM *Standard* C 236) or the calibrated hot box (ASTM *Standard* C 976).

Tables 1 through 6 list thermal values, which may be used to calculate thermal resistances of building walls, floors, and ceilings. The values shown in these tables were developed under ideal conditions. In practice, overall thermal performance can be reduced significantly by such factors as improper installation and shrinkage, settling, or compression of the insulation (Tye and Desjarlais 1983, Tye 1985, 1986).

Most values in these tables were obtained by accepted ASTM test methods described in ASTM *Standards* C 177 and C 518 for materials and ASTM *Standards* C 236 and C 976 for building envelope components. Because commercially available materials vary, not all values apply to specific products. (Previous editions of the handbook can be consulted for data on materials no longer commercially available.)

The most accurate method of determining the overall thermal resistance for a combination of building materials assembled as a building envelope component is to test a representative sample by a hot box method. However, all combinations may not be conveniently or economically tested in this manner. For many simple constructions, calculated R-values agree reasonably well with values determined by hot box measurement.

The performance of materials fabricated in the field is especially subject to the quality of workmanship during construction and installation. Good workmanship becomes increasingly important as the insulation requirement becomes greater. Therefore, some engineers include additional insulation or other safety factors based on experience in their design.

Figure 1 shows how convection affects surface conductance of several materials. Other tests on smooth surfaces show that the average value of the convection part of conductance decreases as the length of the surface increases.

Table 1 Surface Conductances and Resistances for Air

Position of Surface	Direction of Heat Flow	Surface Emittance, ϵ: Nonreflective $\epsilon = 0.90$ h_i	R	Reflective $\epsilon = 0.20$ h_i	R	Reflective $\epsilon = 0.05$ h_i	R
STILL AIR							
Horizontal	Upward	1.63	0.61	0.91	1.10	0.76	1.32
Sloping—45°	Upward	1.60	0.62	0.88	1.14	0.73	1.37
Vertical	Horizontal	1.46	0.68	0.74	1.35	0.59	1.70
Sloping—45°	Downward	1.32	0.76	0.60	1.67	0.45	2.22
Horizontal	Downward	1.08	0.92	0.37	2.70	0.22	4.55
MOVING AIR (Any position)		h_o	R	h_o	R	h_o	R
15-mph Wind (for winter)	Any	6.00	0.17	—	—	—	—
7.5-mph Wind (for summer)	Any	4.00	0.25	—	—	—	—

Notes:
1. Surface conductance h_i and h_o measured in Btu/h · ft² · °F; resistance R in °F · ft² · h/Btu.
2. No surface has both an air space resistance value and a surface resistance value.
3. For ventilated attics or spaces above ceilings under summer conditions (heat flow down), see Table 5.
4. Conductances are for surfaces of the stated emittance facing virtual blackbody surroundings at the same temperature as the ambient air. Values are based on a surface-air temperature difference of 10°F and for surface temperatures of 70°F.
5. See Chapter 3 for more detailed information, especially Tables 5 and 6, and see Figure 1 for additional data.
6. Condensate can have a significant impact on surface emittance (see Table 3).

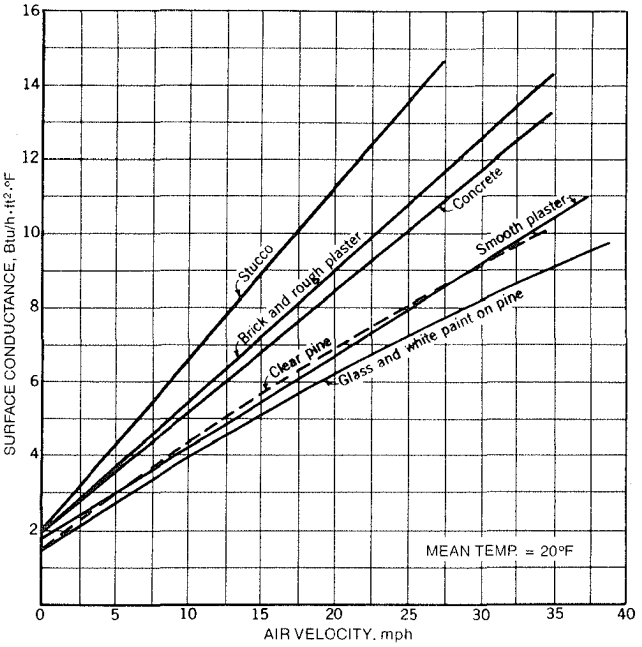

Fig. 1 Surface Conductance for Different 12-Inch-Square Surfaces as Affected by Air Movement

The preparation of this chapter is assigned to TC 4.4, Thermal Insulation and Moisture Retarders.

[a] See Chapter 20, section Factors Affecting Heat Transfer across Air Spaces. Thermal resistance values were determined from the relation, $R = 1/C$, where $C = h_c + \epsilon_{eff} h_r$, h_c is the conduction-convection coefficient, $\epsilon_{eff} h_r$ is the radiation coefficient $\equiv 0.00686\,\epsilon_{eff}\,[(t_m + 460)/100]^3$, and t_m is the mean temperature of the air space. Values for h_c were determined from data developed by Robinson *et al.* (1954). Equations (5) through (7) in Yarbrough (1983) show the data in Table 2 in analytic form. For extrapolation from Table 2 to air spaces less than 0.5 in. (as in insulating window glass), assume $h_c = 0.159\,(1 + 0.0016\,t_m)/l$ where l is the air space thickness in inches, and h_c is heat transfer through the air space only.

[b] Values are based on data presented by Robinson *et al.* (1954). (Also see Chapter 3, Tables 3 and 4, and Chapter 39). Values apply for ideal conditions, *i.e.*, air spaces of uniform thickness bounded by plane, smooth, parallel surfaces with no air leakage to or from the space. When accurate values are required, use overall U-factors determined through calibrated hot box (ASTM C 976) or guarded hot box (ASTM C 236) testing. Thermal resistance values for multiple air spaces must be based on careful estimates of mean temperature differences for each air space.

[c] A single resistance value cannot account for multiple air spaces; each air space requires a separate resistance calculation that applies only for the established boundary conditions. Resistances of horizontal spaces with heat flow downward are substantially independent of temperature difference.

[d] Interpolation is permissible for other values of mean temperature, temperature difference, and effective emittance ϵ_{eff}. Interpolation and moderate extrapolation for air spaces greater than 3.5 in. are also permissible.

[e] Effective emittance ϵ_{eff} of the air space is given by $1/\epsilon_{eff} = 1/\epsilon_1 + 1/\epsilon_2 - 1$, where ϵ_1 and ϵ_2 are the emittances of the surfaces of the air space (see Table 3).

Vapor retarders, outlined in Chapters 20 and 21, require special attention. Moisture from condensation or other sources may reduce the thermal resistance of insulation, but the effect of moisture must be determined for each material. For example, some materials with large air spaces are not affected significantly if the moisture content is less than 10% by weight, while the effect of moisture on other materials is approximately linear.

Ideal conditions of components and installations are assumed in calculating overall R-values (*i.e.*, insulating materials are of uniform nominal thickness and thermal resistance, air spaces are of uniform thickness and surface temperature, moisture effects are not involved, and installation details are in accordance with design). The National Bureau of Standards' Building Materials and Structures Report BMS 151 shows that measured values differ from calculated values for certain insulated constructions. For this reason, some engineers decrease the calculated R-values a moderate amount to account for departures of constructions from requirements and practices.

Tables 2 and 3 give values for well-sealed systems constructed with care. Field applications can differ substantially from laboratory test conditions. Air gaps in these insulation systems can seriously degrade thermal performance as a result of air movement due to both natural and forced convection. Sabine *et al.* (1975) found that the tabular values are not necessarily additive for multiple-layer, low-emittance air spaces, and tests on actual constructions should be conducted to accurately determine thermal resistance values.

Values for foil insulation products supplied by manufacturers must also be used with caution because they apply only to systems that are identical to the configuration in which the product was tested. In addition, surface oxidation, dust accumulation, condensation, and other factors that change the condition of the low-emittance surface can reduce the thermal effectiveness of these insulation systems (Moroz 1951, Hooper and Moroz 1952). Deterioration results from contact with several types of solutions, either acidic or basic (*e.g.*, wet cement mortar or the preservatives found in decay-resistant lumber). Polluted environments may cause rapid and severe material degradation. However, site inspections show a predominance of well-preserved installations and only a small number of cases in which rapid and severe deterioration has occurred. An extensive review of the reflective building insulation system performance literature is provided by Goss and Miller (1989).

Table 3 Emittance Values of Various Surfaces and Effective Emittances of Air Spaces[a]

Surface	Average Emittance ϵ	Effective Emittance ϵ_{eff} of Air Space: One Surface Emittance ϵ; Other, 0.9	Effective Emittance ϵ_{eff} of Air Space: Both Surfaces Emittance ϵ
Aluminum foil, bright	0.05	0.05	0.03
Aluminum foil, with condensate just visible (> 0.7gr/ft^2)	0.30[b]	0.29	—
Aluminum foil, with condensate clearly visible (> 2.9 gr/ft^2)	0.70[b]	0.65	—
Aluminum sheet	0.12	0.12	0.06
Aluminum coated paper, polished	0.20	0.20	0.11
Steel, galvanized, bright	0.25	0.24	0.15
Aluminum paint	0.50	0.47	0.35
Building materials: wood, paper, masonry, nonmetallic paints	0.90	0.82	0.82
Regular glass	0.84	0.77	0.72

[a]These values apply in the 4 to 40 μm range of the electromagnetic spectrum.

[b]Values are based on data presented by Bassett and Trethowen (1984).

CALCULATING OVERALL THERMAL RESISTANCES

Relatively small conductive elements within an insulating layer or thermal bridges can substantially reduce the average thermal resistance of a component. Examples include wood and metal studs in frame walls, concrete webs in concrete masonry walls, and metal ties or other elements in insulated wall panels. The following examples illustrate how to calculate R-values and U-factors for components containing thermal bridges.

The following conditions are assumed in calculating the design R-values:

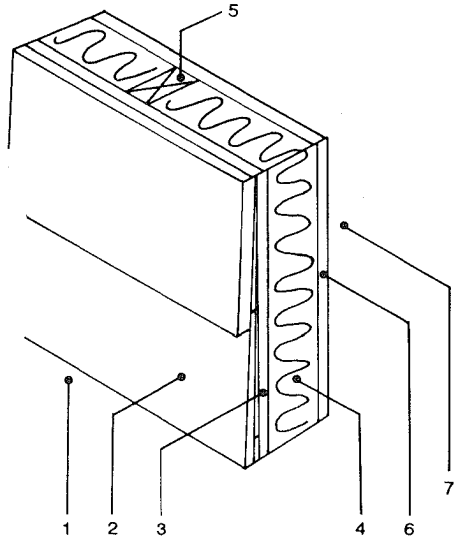
- Equilibrium or steady-state heat transfer, disregarding effects of heat storage
- Surrounding surfaces at ambient air temperature
- Exterior wind velocity of 15 mph for winter (surface with R = 0.17 °F · ft^2 · h/Btu) and 7.5 mph for summer (surface with R = 0.25 °F · ft^2 · h/Btu)
- Surface emittance of ordinary building materials is 0.90

Wood Frame Walls

The average overall R-values and U-factors of wood frame walls can be calculated by assuming either parallel heat flow paths through areas with different thermal resistances or isothermal planes. Equations (1) through (5) from Chapter 20 are used.

For stud walls 16 in. on center (OC), the fraction of insulated cavity is about 0.75; the fraction of studs, plates, and sills is 0.21; and the fraction of headers is 0.04. For studs 24 in. OC, the respective values are 0.78, 0.18, and 0.04. These fractions contain an allowance for multiple studs, plates, sills, extra framing around windows, headers, and band joists.

Example 1A. Calculate the U-factor of the 2 by 4 stud wall shown in Figure 2. The studs are at 16 in. OC. There is 3.5-in. mineral fiber batt insulation (R-13) in the stud space. The inside finish is 0.5-in. gypsum wallboard; the outside is finished with rigid foam insulating sheathing (R-4) and 0.5-in. by 8-in. wood bevel lapped siding. The insulated cavity occupies approxi-



1. Outside surface
2. Wood bevel lapped siding
3. Sheathing (rigid foam insulation, Example 1A; wood fiberboard, Example 1B)
4. Mineral fiber batt insulation
5. Wood stud (nominal 2×4, Example 1A; nominal 2×6, Example 1B)
6. Gypsum wallboard
7. Inside surface

Fig. 2 Insulated Wood Frame Wall (Examples 1A and B)

mately 75% of the transmission area; the studs, plates, and sills occupy 21%; and the headers occupy 4%.

Solution: Obtain the R-values of the various building elements from Tables 1 and 4. Assume the R-value of the wood framing is R-1.25 per inch. Also, assume the headers are solid wood, in this case, and group them with the studs, plates, and sills.

Element	R (Insulated Cavity)	R (Studs, Plates, and Headers)
1. Outside surface, 15 mph wind	0.17	0.17
2. Wood bevel lapped siding	0.81	0.81
3. Rigid foam insulating sheathing	4.0	4.0
4. Mineral fiber batt insulation, 3.5 in.	13.0	—
5. Wood stud, nominal 2 × 4	—	4.38
6. Gypsum wallboard, 0.5 in.	0.45	0.45
7. Inside surface, still air	0.68	0.68
	R_1 = 19.11	R_2 = 10.49

Since the U-factor is the reciprocal of R-value, $U_1 = 0.052$ and $U_2 = 0.095$ Btu/·h·ft^2·°F.

If the wood framing (thermal bridging) is not included, Equation (3) from Chapter 20 may be used to calculate the U-factor of the wall as follows:

$$U_{av} = U_1 = 1/R_1 = 0.052 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

If the wood framing is accounted for using the parallel flow method, the U-factor of the wall is determined using Equation (5) from Chapter 20 as follows:

$$U_{av} = (0.75 \times 0.052) + (0.25 \times 0.095) = 0.063 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

If the wood framing is included using the isothermal planes method, the U-factor of the wall is determined using Equations (2) and (3) from Chapter 20 as follows:

$$R_{T(av)} = 4.98 + 1/[(0.75/13.0) + (0.25/4.38)] + 1.13$$
$$= 14.82 °\text{F} \cdot \text{ft}^2 \cdot \text{h/Btu}$$
$$U_{av} = 0.067 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

For a frame wall with a 24-in. OC stud space, the average overall R-value becomes 15.18 °F·ft^2·h/Btu. Similar calculation procedures can be used to evaluate other wall designs.

Example 1B. Calculate the U-factor of a 2 by 6 stud wall, similar to the one considered in Example IA, except that the sheathing is 0.5-in. wood fiberboard and the studs are at 24 in. OC. There is 5.5-in. mineral fiber batt insulation (R-21) in the stud space. Assume the headers are double 2 by 8 framing (with a 0.5-in. air space), with a 2.0-in. air space between the headers and the wallboard.

Solution: Obtain the R-values of the various building elements from Tables 1 and 4. Assume the R-value of the wood framing is 1.25 per inch. In this case, the headers must be treated separately.

Element	R (Insulated Cavity)	R (Studs and Plates)	R (Headers)
1. Outside surface, 15 mph wind	0.17	0.17	0.17
2. Wood bevel lapped siding	0.81	0.81	0.81
3. Wood fiberboard sheathing, 0.5 in.	1.32	1.32	1.32
4. Mineral fiber batt insulation, 5.5 in.	21.0	—	—
5. Wood stud, nominal 2 × 6	—	6.88	—
6. Wood headers, double 2 × 8	—	—	3.75
7. Air space, 0.5 in.	—	—	0.90
8. Air space, 2 in.	—	—	0.90
9. Gypsum wallboard, 0.5 in.	0.45	0.45	0.45
10. Inside surface, still air	0.68	0.68	0.68
	R_1 = 24.43	R_2 = 10.31	R_3 = 8.98

Since U-factor is the reciprocal of R-value, $U_1 = 0.041$, $U_2 = 0.097$, and $U_3 = 0.111$ Btu/h·ft^2·°F.

If the wood framing is accounted for using the parallel flow method, the U-factor of the wall is determined using Equation (5) from Chapter 20 as follows:

$$U_{av} = (0.78 \times 0.041) + (0.18 \times 0.097) + (0.04 \times 0.111)$$
$$= 0.054 \text{ Btu} \cdot \text{h} \cdot \text{ft}^2 \cdot °\text{F}$$

If the wood framing is included using the isothermal planes method, the U-factor of the wall is determined using Equations (2) and (3) from Chapter 20 as follows:

$$R_{T(av)} = 2.30 + 1/[(0.78/21.0) + (0.18/6.88) + (0.04/5.55)] + 1.13$$
$$= 17.61 °\text{F} \cdot \text{ft}^2 \cdot \text{h/Btu}$$
$$U_{av} = 0.057 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

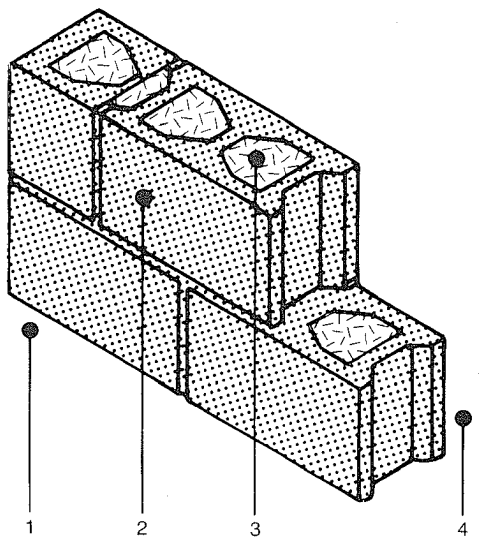
If the headers are insulated with R-10 insulation, the average overall R-value becomes 18.57 °F·ft^2·h/Btu.

For a frame wall with a 16-in. OC stud space and uninsulated headers, the average overall R-value becomes 17.05 °F·ft^2·h/Btu. If the headers are insulated with R-10 insulation, the average overall R-value becomes 17.93 °F·ft^2·h/Btu. Similar calculation procedures can be used to evaluate other wall designs.

Masonry Walls

The average overall R-values of masonry walls can be estimated by assuming a combination of layers in series, one or more of which provides parallel paths. This method is used because heat flows laterally through block face shells so that transverse isothermal planes result. Average total resistance $R_{T(av)}$ is the sum of the resistances of the layers between such planes, each layer calculated as shown in Example 2.

Example 2. Calculate the overall thermal resistance and average U-factor of the 7-5/8-in. thick insulated concrete block wall shown in Figure 3. The two-core block has an average web thickness of 1-in. and a face shell thickness of 1-1/4-in. Overall block dimensions are 7-5/8 by 7-5/8 by 15-5/8 in. Measured thermal resistances of 112 lb/ft^3 concrete and 7 lb/ft^3 expanded perlite insulation are 0.10 and 2.90 °F·ft^2·h/Btu per inch, respectively.



1. Outside surface (15 mph wind)
2. Concrete block
3. Expanded perlite insulation
4. Inside surface (still air)

Fig. 3 Insulated Concrete Block Wall (Example 2)

Solution: The equation used to determine the overall thermal resistance of the insulated concrete block wall is derived from Equations (2) and (5) from Chapter 20 and is given below:

$$R_{T(av)} = R_i + R_f + \left(\frac{a_w}{R_w} + \frac{a_c}{R_c}\right)^{-1} + R_o$$

where

$R_{T(av)}$ = overall thermal resistance based on assumption of isothermal planes
R_i = thermal resistance of inside air surface film (still air)
R_o = thermal resistance of outside air surface film (15 mph wind)
R_f = total thermal resistance of face shells
R_c = thermal resistance of cores between face shells
R_w = thermal resistance of webs between face shells
a_w = fraction of total area transverse to heat flow represented by webs of blocks
a_c = fraction of total area transverse to heat flow represented by cores of blocks

From the information given and the data in Table 1, determine the values needed to compute the overall thermal resistance.

$R_i = 0.68$
$R_o = 0.17$
$R_f = (2)(1.25)(0.10) = 0.25$
$R_c = (5.125)(2.90) = 14.86$
$R_w = (5.125)(0.10) = 0.51$
$a_w = 3/15.625 = 0.192$
$a_c = 12.625/15.625 = 0.808$

Using the equation given, the overall thermal resistance and average U-factor are calculated as follows:

$$R_{T(av)} = 0.68 + 0.25 + (0.51)(14.86)/[(0.808)(0.51) + (0.192)(14.86)] + 0.17$$
$$= 0.68 + 0.25 + 2.33 + 0.17 = 3.43\,°F \cdot ft^2 \cdot h/Btu$$
$$U_{av} = 1/3.43 = 0.29\ Btu/h \cdot ft^2 \cdot °F$$

Based on guarded hot box tests of this wall without mortar joints, Tye and Spinney (1980) measured the average R-value for this insulated concrete block wall as 3.13 °F · ft² · h/Btu.

Assuming parallel heat flow only, the calculated resistance is usually higher than that calculated on the assumption of isothermal planes. The actual resistance generally is some value between the two calculated values. In the absence of test values, examination of the construction usually reveals whether a value closer to the higher or lower calculated R-value should be used. Generally, if the construction contains a layer in which lateral conduction is high compared with transmittance through the construction, the calculation with isothermal planes should be used. If the construction has no layer of high lateral conductance, the parallel heat flow calculation should be used.

Hot box tests of insulated and uninsulated masonry walls constructed with block of conventional configuration show that thermal resistances calculated using the isothermal planes heat flow method agree well with measured values (Van Geem 1985, Valore 1980, Shu *et al.* 1979). Neglecting horizontal mortar joints in conventional block can result in thermal transmittance values up to 16% lower than actual, depending on the density and thermal properties of the masonry, and 1 to 6% lower, depending on the core insulation material (Van Geem 1985, McIntyre 1984). For aerated concrete block walls, other solid masonry, and multicore block walls with full mortar joints, neglecting mortar joints can cause errors in R-values up to 40% (Valore 1988). Horizontal mortar joints usually found in concrete block wall construction are neglected in Example 2.

Panels Containing Metal

Curtain wall constructions often include metallic and other thermal bridges. The thermal resistance of panels can be significantly reduced by metallic thermal bridges. However, the capacity of the adjacent facing materials to transmit heat transversely to the metal is limited, and some contact resistance between all materials in contact limits the reduction. Contact resistances in building structures are only 0.06 to 0.6 °F · ft² · h/Btu—too small to be of concern in many cases. However, the contact resistances of steel framing members are important. Also, in many cases (as illustrated in Example 3), the area of metal in contact with the facing greatly exceeds the thickness of the metal which mitigates the influence.

Thermal characteristics for panels of sandwich construction can be computed by combining the thermal resistances of the various layers. However, few panels are true sandwich constructions; many have ribs and stiffeners that create complicated heat flow paths. R-values for the assembled sections should be determined on a representative sample by using a hot box method. If the sample is a wall section with air cavities on both sides of fibrous insulation, the sample must be of representative height since convective airflow can contribute significantly to heat flow through the test section. Computer modeling can also be useful, but all heat transfer mechanisms must be considered.

In Example 3, the metal member is only 0.020 in. thick, but it is in contact with adjacent facings over a 1.25 in.-wide area. The steel member is 3.50 in. deep, has a thermal resistance of approximately 0.011 °F · ft² · h/Btu, and is virtually isothermal. The calculation involves careful selection of the appropriate thickness for the steel member. If the member is assumed to be 0.020 in. thick, the fact that the flange transmits heat to the adjacent facing is ignored, and the heat flow through the steel is underestimated. If the member is assumed to be 1.25 in. thick, the heat flow through the steel is overestimated. In Example 3, the steel member behaves in much the same way as a rectangular member 1.25 in. thick and 3.50 in. deep with a thermal resistance of 0.69 °F · ft² · h/Btu [(1.25/0.020) × 0.011] does. The Building Research Association of New Zealand (BRANZ) commonly uses this approximation.

Example 3. Calculate the C-factor of the insulated steel frame wall shown in Figure 4. Assume that the steel member has an R-value of 0.69 °F · ft² · h/Btu and that the framing behaves as though it occupies approximately 8% of the transmission area.

Solution: Obtain the R-values of the various building elements from Table 4.

Element	R (Insul.)	R (Framing)
1. 0.5-in. gypsum wallboard	0.45	0.45
2. 3.5-in. mineral fiber batt insulation	11	—
3. Steel framing member	—	0.69
4. 0.5-in. gypsum wallboard	0.45	0.45
	$R_1 = 11.90$	$R_2 = 1.59$

Therefore, $C_1 = 0.084$; $C_2 = 0.629$ Btu/h · ft² °F.

If the steel framing (thermal bridging) is not considered, the C-factor of the wall is calculated using Equation (3) from Chapter 20 as follows:

$$C_{av} = C_1 = 1/R_1 = 0.084\ Btu/h \cdot ft^2 \cdot °F$$

[a] Values are for a mean temperature of 75 °F. Representative values for dry materials are intended as design (not specification) values for materials in normal use. Thermal values of insulating materials may differ from design values depending on their in-situ properties (*e.g.*, density and moisture content, orientation, etc.) and variability experienced during manufacture. For properties of a particular product, use the value supplied by the manufacturer or by unbiased tests.

[b] To obtain thermal conductivities in Btu/h·ft·°F, divide the *k*-factor by 12 in./ft.

[c] Resistance values are the reciprocals of *C* before rounding off *C* to two decimal places.

[d] Lewis (1967).

[e] U.S. Department of Agriculture (1974).

[f] Does not include paper backing and facing, if any. Where insulation forms a boundary (reflective or otherwise) of an airspace, see Tables 2 and 3 for the insulating value of an airspace with the appropriate effective emittance and temperature conditions of the space.

[g] Conductivity varies with fiber diameter. (See Chapter 20, Factors Affecting Thermal Performance.) Batt, blanket, and loose-fill mineral fiber insulations are manufactured to achieve specified R-values, the most common of which are listed in the table. Due to differences in manufacturing processes and materials, the product thicknesses, densities, and thermal conductivities vary over considerable ranges for a specified R-value.

[h] This material is relatively new and data are based on limited testing.

[i] For additional information, see Society of Plastics Engineers (SPI) *Bulletin* U108. Values are for aged, unfaced board stock. For change in conductivity with age of expanded polyurethane/polyisocyanurate, see Chapter 20, Factors Affecting Thermal Performance.

[j] Values are for aged products with gas-impermeable facers on the two major surfaces. An aluminum foil facer of 0.001 in. thickness or greater is generally considered impermeable to gases. For change in conductivity with age of expanded polyisocyanurate, see Chapter 20, Factors Affecting Thermal Performance, and SPI *Bulletin* U108.

[k] Insulating values of acoustical tile vary, depending on density of the board and on type, size, and depth of perforations.

[l] Values for fully grouted block may be approximated using values for concrete with a similar unit weight.

[m] Values for metal siding applied over flat surfaces vary widely, depending on amount of ventilation of airspace beneath the siding; whether airspace is reflective of non-reflective; and on thickness, type, and application of insulating backing-board used. Values given are averages for use as design guides, and were obained from several guarded hot box tests (ASTM C236) or calibrated hot box (ASTM C976) on hollow-backed types and types made using backing-boards of wood fiber, foamed plastic, and glass fiber. Departures of ±50% or more from the values given may occur.

[n] See Adams (1971), MacLean (1941), and Wilkes (1979). The conductivity values listed are for heat transfer across the grain. The thermal conductivity of wood varies linearly with the density, and the density ranges listed are those normally found for the wood species given. If the density of the wood species is not known, use the mean conductivity value. For extrapolation to other moisture contents, the following empirical equation developed by Wilkes (1979) may be used:

$$k = 0.1791 + \frac{(1.874 \times 10^{-2} + 5.753 \times 10^{-4} M)\rho}{1 + 0.01M}$$

where ρ is density of the moist wood in lb/ft³, and M is the moisture content in percent.

[o] From Wilkes (1979), an empirical equation for the specific heat of moist wood at 75 °F is as follows:

$$c_p = \frac{(0.299 + 0.01M)}{(1 + 0.01M)} + \Delta c_p$$

where Δc_p accounts for the heat of sorption and is denoted by

$$\Delta c_p = M(1.921 \times 10^{-3} - 3.168 \times 10^{-5} M)$$

where M is the moisture content in percent by mass.

If the steel framing is accounted for using the parallel flow method, the C-factor of the wall is determined using Equation (5) from Chapter 20 as follows:

$$C_{av} = (0.92 \times 0.084) + (0.08 \times 0.629)$$
$$= 0.128 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$
$$R_{T(av)} = 7.81 °\text{F} \cdot \text{ft}^2 \cdot \text{h/Btu}$$

If the steel framing is included using the isothermal planes method, the C-factor of the wall is determined using Equations (2) and (3) from Chapter 20 as follows:

$$R_{T(av)} = 0.45 + 1/[(0.92/11.00) + (0.08/0.69)] + 0.45$$
$$= 5.91 °\text{F} \cdot \text{ft}^2 \cdot \text{h/Btu}$$
$$C_{av} = 0.169 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

For this insulated steel frame wall, Farouk and Larson (1983) measured an average R-value of 6.61 °F · ft² · h/Btu.

In ASHRAE/IES *Standard* 90.1-1989, Energy Efficient Design of New Buildings except New Low-Rise Residential Buildings, one method given for determining the thermal resistance of wall assemblies containing metal framing involves using a parallel path correction factor F_c. The F_c values are included in Table 8C-2 of ASHRAE/IES *Standard* 90.1-1989. For 2 by 4 steel framing, 16 in. on center, $F_c = 0.50$. Using the correction factor method, an R-value of 6.40 · °F · ft² · h/Btu [0.45 + 11(0.50) + 0.45] is obtained for the wall described in Example 3.

Zone Method of Calculation

For structures with widely spaced metal members of substantial cross-sectional area, calculation by the isothermal planes method can result in thermal resistance values that are too low. For these constructions, the *zone method* can be used. This method involves two separate computations—one for a chosen limited portion, Zone A, containing the highly conductive element; the other for the remaining portion of simpler construction, Zone B. The two computations are then combined using the parallel flow method, and the average transmittance per unit overall area is calculated. The basic laws of heat transfer are applied by adding the area conductances *CA* of elements in parallel, and adding area resistances *R/A* of elements in series.

The surface shape of Zone A is determined by the metal element. For a metal beam (see Figure 5), the Zone A surface is a strip of width *W* that is centered on the beam. For a rod perpendicular to panel surfaces, it is a circle of diameter *W*. The value of *W* is calculated from Equation (1), which is empirical. The value of *d* should not be less than 0.5 in. for still air.

$$W = m + 2d \quad (1)$$

where

m = width or diameter of metal heat path terminal, in.
d = distance from panel surface to metal, in.

Generally, the value of *W* should be calculated using Equation (1) for each end of the metal heat path; the larger value, within the limits of the basic area, should be used as illustrated in Example 4.

Example 4. Calculate transmittance of the roof deck shown in Figure 5. Tee-bars at 24 in. OC support glass fiber form boards, gypsum concrete, and built-up roofing. Conductivities of components are: steel, 314.4 Btu · in/h · ft² · °F; gypsum concrete, 1.66 Btu · in/h · ft² · °F; and glass fiber form board, 0.25 Btu · in/h · ft² · °F. Conductance of built-up roofing is 3.00 Btu/h · ft² · °F.

Solution: The basic area is 2 ft² (24 in. by 12 in.) with a tee-bar (12 in. long) across the middle. This area is divided into Zones A and B.

Zone A is determined from Equation (1) as follows:

Top side $W = m + 2d = 0.625 + (2 \times 1.5) = 3.625$ in.
Bottom side $W = m + 2d = 2.0 + (2 \times 0.5) = 3.0$ in.

Using the larger value of *W*, the area of Zone A is $(12 \times 3.625)/144 = 0.302$ ft². The area of Zone B is $2.0 - 0.302 = 1.698$ ft².

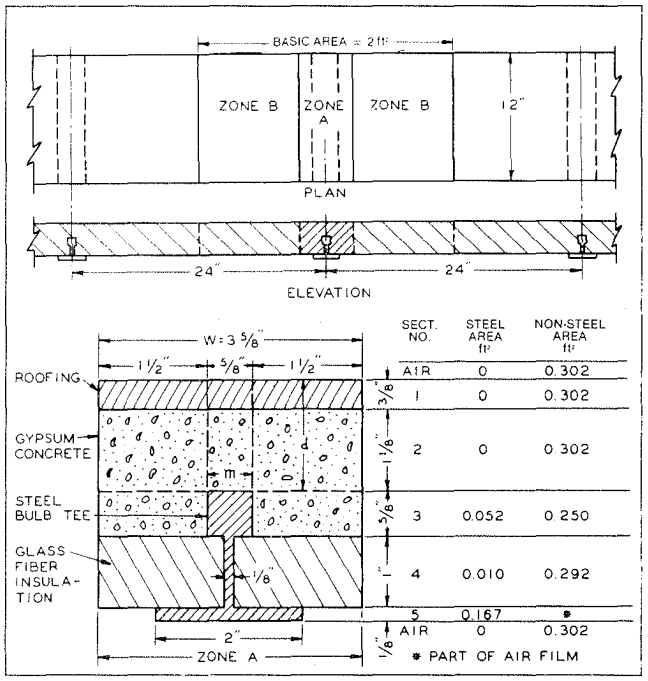

Fig. 5 Gypsum Roof Deck on Bulb Tees (Example 4)

To determine area transmittance for Zone A, divide the structure within the zone into five sections parallel to the top and bottom surfaces (Figure 5). The area conductance *CA* of each section is calculated by adding the area conductances of its metal and nonmetal paths. Area conductances of the sections are converted to area resistances *R/A* and added to obtain the total resistance of Zone A.

Section	Area × Conductance	= *CA*	$\frac{1}{CA}$ = $\frac{R}{A}$
Air (outside, 15 mph)	0.302 × 6.00	1.81	0.55
No. 1, Roofing	0.302 × 3.00	0.906	1.10
No. 2, Gypsum concrete	0.302 × 1.66/1.125	0.446	2.24
No. 3, Steel	0.052 × 314.4/0.625	26.2	0.04
No. 3, Gypsum concrete	0.250 × 1.66/0.625	0.664	
No. 4, Steel	0.010 × 314.4/1.00	3.14	0.31
No. 4, Glass fiberboard	0.292 × 0.25/1.00	0.073	
No. 5, Steel	0.167 × 314.4/0.125	420.0	0.002
Air (inside)	0.302 × 1.63	0.492	2.03
		Total *R/A* =	6.27

Area transmittance of Zone A = $1/(R/A) = 1/6.27 = 0.159$.

For Zone B, the unit resistances are added and then converted to area transmittance, as shown in the following table.

Section	Resistance, *R*
Air (outside, 15 mph)	1/6.00 = 0.17
Roofing	1/3.00 = 0.33
Gypsum concrete	1.75/1.66 = 1.05
Glass fiberboard	1.00/0.25 = 4.00
Air (inside)	1/1.63 = 0.61
Total resistance	= 6.16

Since unit transmittance = $1/R = 0.162$, the total area transmittance *UA* is calculated as follows:

Zone B = 1.698 × 0.162 = 0.275
Zone A = 0.159
Total area transmittance of basic area = 0.434
Transmittance per ft² = 0.434/2.0 = 0.217
Resistance per ft² = 4.61

Overall R-values of 4.57 and 4.85 °F · ft² · h/Btu have been measured in two guarded hot box tests of a similar construction.

When the steel member represents a relatively large proportion of the total heat flow path, as in Example 4, detailed calculations of resistance in sections 3, 4, and 5 of Zone A are unnecessary; if only the steel member is considered, the final result of Example 4 is the same. However, if the heat flow path represented by the steel member is small, as for a tie rod, detailed calculations for sections 3, 4, and 5 are necessary. A panel with an internal metallic structure and bonded on one or both sides to a metal skin or covering presents special problems of lateral heat flow not covered in the zone method.

Ceilings and Roofs

The overall R-value for ceilings of wood frame flat roofs can be calculated using Equations (1) through (5) from Chapter 20. Properties of the materials are found in Tables 1, 2, 3, and 4. The fraction of framing is assumed to be 0.10 for joists at 16 in. OC and 0.07 for joists at 24 in. OC. The calculation procedure is similar to that shown in Example 1. Note that if the ceiling contains plane air spaces (see Table 2), the resistance depends on the direction of heat flow, *i.e.*, whether the calculation is for a winter (heat flow up) or summer (heat flow down) condition.

For ceilings of pitched roofs under winter conditions, calculate the R-value of the ceiling using the procedure for flat roofs. The heat loss from these ceilings can be obtained using a calculated attic temperature (see Chapter 25). Table 5 can be used to determine the effective resistance of the attic space under summer conditions for varying conditions of ventilation air temperature, airflow direction and rates, ceiling resistance, roof or sol-air temperatures, and surface emittances (Joy 1958).

The R-value is the total resistance obtained by adding the ceiling and effective attic resistances. The applicable temperature difference is that difference between room air and sol-air temperatures or between room air and roof temperatures (see Table 5, footnote f). Table 5 can be used for pitched and flat residential roofs over attic spaces. When an attic has a floor, the ceiling resistance should account for the complete ceiling-floor construction.

Windows and Doors

The U-factors given in Table 5 of Chapter 27 are for vertical glazing (*e.g.*, windows, glass in exterior doors, glass doors, and skylights). The values were computed using procedures outlined in Chapter 27. The U-factors in Table 6 are for exterior wood and steel doors. The values given for wood doors were calculated, and those for steel doors were taken from hot box tests (Sabine *et al.* 1975, Yellott 1965) or from manufacturers' test reports. An outdoor surface conductance of 6.0 Btu/h · ft² · °F was used, and the indoor surface conductance was taken as 1.46 Btu/h · ft² · °F for vertical surfaces with horizontal heat flow. All values given are for exterior doors without glazing. If an exterior door contains glazing, the glazing should be analyzed as a window, as illustrated in Example 5.

Example 5. Determine the U-factor of a fixed wood frame residential window containing double insulating glass with 0.5-in. air space and metal spacer for winter conditions.

Solution: From Chapter 27, Table 5, the U-factor of the center of the glass portion only is 0.49 Btu/h · ft² · °F for glazing 1D6, double glazing, 0.5-in. air space. The wood frame of the window must also be

Table 5 Effective Thermal Resistance of Ventilated Attics[a] (Summer Condition)

[a] Although the term effective resistance is commonly used when there is attic ventilation, this table includes values for situations with no ventilation. The effective resistance of the attic added to the resistance ($1/U$) of the ceiling yields the effective resistance of this combination based on sol-air (see Chapter 26) and room temperatures. These values apply to wood frame construction with a roof deck and roofing that has a conductance of 1.0 Btu/h · ft² · °F.

[b] This condition cannot be achieved in the field unless extreme measures are taken to tightly seal the attic.

[c] Based on air discharging outward from attic.

[d] When attic ventilation meets the requirements stated in Chapter 23, 0.1 cfm/ft² is assumed as the natural summer ventilation rate.

[e] When determining ceiling resistance, do not add the effect of a reflective surface facing the attic, as it is accounted for in Table 5, Part B.

[f] Roof surface temperature rather than sol-air temperature (see Chapter 26) can be used if 0.25 is subtracted from the attic resistance shown.

[g] Surfaces with effective emittance $\epsilon_{eff} = 0.05$ between ceiling joists facing attic space.

Table 6 Transmission Coefficients U for Wood and Steel Doors, Btu/h · ft² · °F

Nominal Door Thickness, in.	Description	No Storm Door	Wood Storm Door[c]	Metal Storm Door[d]
Wood Doors[a,b]				
1-3/8	Panel door with 7/16-in. panels[e]	0.57	0.33	0.37
1-3/8	Hollow core flush door	0.47	0.30	0.32
1-3/8	Solid core flush door	0.39	0.26	0.28
1-3/4	Panel door with 7/16-in. panels[e]	0.54	0.32	0.36
1-3/4	Hollow core flush door	0.46	0.29	0.32
1-3/4	Panel door with 1-1/8-in. panels[e]	0.39	0.26	0.28
1-3/4	Solid core flush door	0.40	—	0.26
2-1/4	Solid core flush door	0.27	0.20	0.21
Steel Doors[b]				
1-3/4	Fiberglass or mineral wool core with steel stiffeners, no thermal break[f]	0.60	—	—
1-3/4	Paper honeycomb core without thermal break[f]	0.56	—	—
1-3/4	Solid urethane foam core without thermal break[a]	0.40	—	—
1-3/4	Solid fire rated mineral fiberboard core without thermal break[f]	0.38	—	—
1-3/4	Polystyrene core without thermal break (18 gage commercial steel)[f]	0.35	—	—
1-3/4	Polyurethane core without thermal break (18 gage commercial steel)[f]	0.29	—	—
1-3/4	Polyurethane core without thermal break (24 gage residential steel)[f]	0.29	—	—
1-3/4	Polyurethane core with thermal break and wood perimeter (24 gage residential steel)[f]	0.20	—	—
1-3/4	Solid urethane foam core with thermal break[a]	0.20	—	0.16

Note: All U-factors for exterior doors in this table are for doors with no glazing, except for the storm doors which are in addition to the main exterior door. Any glazing area in exterior doors should be included with the appropriate glass type and analyzed as a window (see Chapter 27). Interpolation and moderate extrapolation are permitted for door thicknesses other than those specified.

[a] Values are based on a nominal 32 by 80 in. door size with no glazing.

[b] Outside air conditions: 15 mph wind speed, 0°F air temperature; inside air conditions: natural convection, 70°F air temperature.

[c] Values for wood storm door are for approximately 50% glass area.

[d] Values for metal storm door are for any percent glass area.

[e] 55% panel area.

[f] ASTM C 236 hotbox data on a nominal 3 by 7 ft door size with no glazing.

considered when determining the window U-factor. Referring to Table 5 in Chapter 27, for a fixed wood frame window with a 0.5-in. air space and metal spacer, the U-factor is given as 0.51 Btu/h · ft² · °F.

All R-values are approximate, since a significant portion of the resistance of a window or door is contained in the air film resistances, and some parameters that may have important effects are not considered. For example, the listed U-factors assume the surface temperatures of surrounding bodies are equal to the ambient air temperature. However, the indoor surface of a window or door in an actual installation may be exposed to nearby radiating surfaces, such as radiant heating panels, or opposite walls with much higher or lower temperatures than the indoor air. Air movement across the indoor surface of a window or door, such as that caused by nearby heating and cooling outlet grilles, increases the U-factor; and air movement (wind) across the outdoor surface of a window or door also increases the U-factor.

U_o Concept

In Section 4 of ASHRAE *Standard* 90A-1980, Energy Conservation in New Building Design, requirements are stated in terms of U_o, where U_o is the combined thermal transmittance of the respective areas of gross exterior wall, roof or ceiling or both, and floor assemblies. The U_o equation for a wall is as follows:

$$U_o = (U_{wall} A_{wall} + U_{window} A_{window} + U_{door} A_{door})/A_o \quad (2)$$

where

U_o = average thermal transmittance of gross wall area
A_o = gross area of exterior walls
U_{wall} = thermal transmittance of all elements of opaque wall area
A_{wall} = opaque wall area
U_{window} = thermal transmittance of window area (including frame)
A_{window} = window area (including frame)
U_{door} = thermal transmittance of door area
A_{door} = door area

Where more than one type of wall, window, or door is used, the UA term for that exposure should be expanded into its subelements, as shown in Equation (3).

$$\begin{aligned} U_o A_o = {} & U_{wall\,1} A_{wall\,1} + U_{wall\,2} A_{wall\,2} + \cdots + U_{wall\,m} A_{wall\,m} \\ & + U_{window\,1} A_{window\,1} + U_{window\,2} A_{window\,2} + \cdots \\ & + U_{window\,n} A_{window\,n} + U_{door\,1} A_{door\,1} \\ & + U_{door\,2} A_{door\,2} + \cdots + U_{door\,o} A_{door\,o} \end{aligned} \quad (3)$$

Example 6. Calculate U_o for a wall 30 ft by 8 ft, constructed as in Example 1A. The wall contains one window 60 in. by 34 in. and a second window 36 in. by 30 in. Both windows are constructed as in Example 5. The wall also contains a 1.75-in. solid core flush door with a metal storm door 34 in. by 80 in. (U = 0.26 Btu/h · ft² · °F from Table 6).

Solution: The U-factors for the wall and windows were obtained in Examples 1A and 5, respectively. The areas of the different components are:

$$A_{window} = [(60 \times 34) + (36 \times 30)]/144 = 21.7 \text{ ft}^2$$
$$A_{door} = (34 \times 80)/144 = 18.9 \text{ ft}^2$$
$$A_{wall} = (30 \times 8) - (21.7 + 18.9) = 199.4 \text{ ft}^2$$

Therefore, the combined thermal transmittance for the wall is:

$$U_o = \frac{(0.063 \times 199.4) + (0.51 \times 21.7) + (0.26 \times 18.9)}{(30 \times 8)}$$
$$= 0.119 \text{ Btu/h} \cdot \text{ft}^2 \cdot {}^\circ\text{F}$$

Slab-on-Grade and Below-Grade Construction

Heat transfer through basement walls and floors to the ground depends on the following factors: (1) the difference between the air temperature within the room and that of the ground and outside air, (2) the material of the walls or floor, and (3) the thermal

conductivity of the surrounding earth. The latter varies with local conditions and is usually unknown. Because of the great thermal inertia of the surrounding soil, ground temperature varies with depth, and there is a substantial time lag between changes in outdoor air temperatures and corresponding changes in ground temperatures. As a result, ground-coupled heat transfer is less amenable to steady-state representation than above-grade building elements. However, several simplified procedures for estimating ground-coupled heat transfer have been developed. These fall into two principal categories: (1) those that reduce the ground heat transfer problem to a closed form solution, and (2) those that use simple regression equations developed from statistically reduced multidimensional transient analyses.

Closed form solutions, including the ASHRAE arc-length procedure discussed in Chapter 25 by Latta and Boileau (1969), generally reduce the problem to one-dimensional, steady-state heat transfer. These procedures use simple, "effective" U-factors or ground temperatures or both. Methods differ in the various parameters averaged or manipulated to obtain these effective values. Closed form solutions provide acceptable results in climates that have a single dominant season, because the dominant season persists long enough to permit a reasonable approximation of steady-state conditions at shallow depths. The large errors (percentage) that are likely during transition seasons should not seriously affect building design decisions, since these heat flows are relatively insignificant when compared with those of the principal season.

The ASHRAE arc-length procedure is a reliable method for wall heat losses in cold winter climates. Chapter 25 discusses a slab-on-grade floor model developed by one study. Although both procedures give results comparable to transient computer solutions for cold climates, their results for warmer U.S. climates differ substantially.

Research conducted by Hougten *et al.* (1942) and Dill *et al.* (1945) indicates a heat flow of approximately 2.0 Btu/h·ft^2 through an uninsulated concrete basement floor with a temperature difference of 20°F between the basement floor and the air 6 in. above it. A U-factor of 0.10 Btu/h·ft^2·°F is sometimes used for concrete basement floors on the ground. For basement walls below grade, the temperature difference for winter design conditions is greater than for the floor. Test results indicate that at the midheight of the below-grade portion of the basement wall, the unit area heat loss is approximately twice that of the floor.

For concrete slab floors in contact with the ground at grade level, tests indicate that for small floor areas (equal to that of a 25 by 25 ft house) the heat loss can be calculated as proportional to the length of exposed edge rather than total area. This amounts to 0.81 Btu/h per linear foot of exposed edge per °F difference between the indoor air temperature and the average outdoor air temperature. This value can be reduced appreciably by installing insulation under the ground slab and along the edge between the floor and abutting walls. In most calculations, if the perimeter loss is calculated accurately, no other floor losses need to be considered. Chapter 25 contains data for load calculations and heat loss values for below-grade walls and floors at different depths.

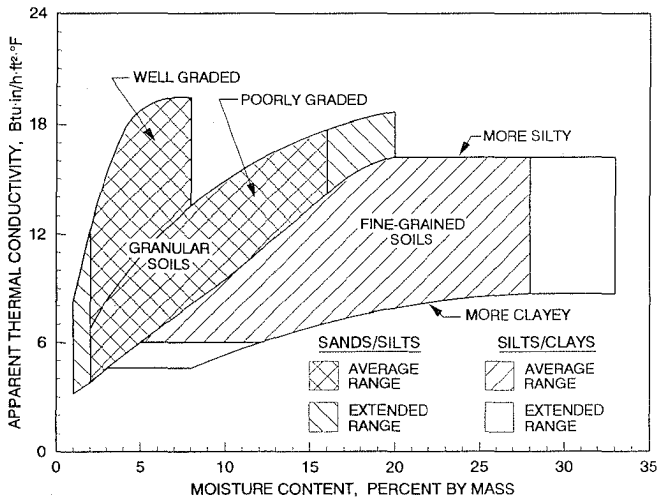

Fig. 6 Trends of Apparent Thermal Conductivity of Moist Soils

The second category of simplified procedures uses transient two-dimensional computer models to generate the ground heat transfer data that are then reduced to compact form by regression analysis (see Mitalas 1982 and 1983, Shipp 1983). These are the most accurate procedures available, but the database is very expensive to generate. In addition, these methods are limited to the range of climates and constructions specifically examined. Extrapolating beyond the outer bounds of the regression surfaces can produce significant errors.

Apparent Thermal Conductivity of Soil

Effective or apparent soil thermal conductivity is difficult to estimate precisely and may change substantially in the same soil at different times due to changed moisture conditions and the presence of freezing temperatures in the soil. Figure 6 shows the typical apparent soil thermal conductivity as a function of moisture content for different general types of soil. The figure is based on data presented in Salomone and Marlowe (1989) using envelopes of thermal behavior coupled with field moisture content ranges for different soil types. In Figure 6, the term well-graded applies to granular soils with good representation of all particle sizes from largest to smallest. The term poorly graded refers to granular soils with either a uniform gradation, in which most particles are about the same size, or a skip (or gap) gradation, in which particles of one or more intermediate sizes are not present.

Although thermal conductivity varies greatly over the complete range of possible moisture contents for a soil, this range can be narrowed if it is assumed that the moisture contents of most field soils lie between the "wilting point" of the soil (*i.e.*, the moisture content of a soil below which a plant cannot alleviate its wilting symptoms) and the "field capacity" of the soil (*i.e.*, the moisture

Table 7 Typical Apparent Thermal Conductivity Values for Soils, Btu·in/h·ft^2·°F

		Recommended Values for Design[a]	
	Normal Range	Low[b]	High[c]
Sands	4.2 to 17.4	5.4	15.6
Silts	6 to 17.4	11.4	15.6
Clays	6 to 11.4	7.8	10.8
Loams	6 to 17.4	6.6	15.6

[a]Reasonable values for use when no site- or soil-specific data are available.
[b]Moderately conservative values for minimum heat loss through soil (*e.g.*, use in soil heat exchanger or earth-contact cooling calculations). Values are from Salomone and Marlowe (1989).
[c]Moderately conservative values for maximum heat loss through soil (*e.g.*, use in peak winter heat loss calculations). Values are from Salomone and Marlowe (1989).

Table 8 Typical Apparent Thermal Conductivity Values for Rocks, Btu·in/h·ft^2·°F

	Normal Range
Pumice, tuff, obsidian	3.6 to 15.6
Basalt	3.6 to 18.0
Shale	6 to 27.6
Granite	12 to 30
Limestone, dolomite, marble	8.4 to 30
Quartzose sandstone	9.6 to 54

content of a soil that has been thoroughly wetted and then drained until the drainage rate has become negligibly small). After a prolonged dry spell, the moisture will be near the wilting point, and after a rainy period, the soil will have a moisture content near its field capacity. The moisture contents at these limits have been studied by many agricultural researchers, and data for different types of soil are given by Salomone and Marlowe (1989) and Kersten (1949). The shaded areas on Figure 6 approximate (1) the full range of moisture contents for different soil types and (2) a range between average values of each limit.

Table 7 gives a summary of design values for thermal conductivities of the basic soil classes. Table 8 gives ranges of thermal conductivity for some basic classes of rock. The value chosen depends on whether heat transfer is being calculated for minimum heat loss through the soil, as in a ground heat exchange system, or a maximum value, as in peak winter heat loss calculations for a basement. Hence, a high and a low value are given for each soil class.

As heat flows through the soil, the moisture tends to move away from the source of heat. This moisture migration provides initial mass transport of heat, but it also dries the soil adjacent to the heat source, hence lowering the apparent thermal conductivity in that zone of soil.

The following trends are typical in a soil when other factors are held constant:

1. k increases with moisture content
2. k increases with increasing dry density of a soil
3. k decreases with increasing organic content of a soil
4. k tends to decrease for soils with uniform gradations and rounded soil grains (because the grain-to-grain contacts are reduced)

Table 9 Typical Water Vapor Permeance and Permeability Values for Common Building Materials[a] (*Concluded*)

Material	Weight, lb/100 ft²	Permeance, Perms			Resistance[h] Rep		
		Dry-Cup	Wet-Cup	Other	Dry-Cup	Wet-Cup	Other

[a]This table permits comparisons of materials; but in the selection of vapor retarder materials, exact values for permeance or permeability should be obtained from the manufacturer or from laboratory tests. The values shown indicate variations among mean values for materials that are similar but of different density, orientation, lot, or source. The values should not be used as design or specification data. Values from dry-cup and wet-cup methods were usually obtained from investigations using ASTM E96 and C355; values shown under others were obtained by two-temperature, special cell, and air velocity methods. Permeance, resistance, permeability, and resistance per unit thickness values are given in the following units:

Permeance	Perm	= gr/h · ft² · in. Hg
Resistance	Rep	= in. Hg · ft² · h/gr
Permeability	Perm-in.	= gr/h · ft² · (in. Hg/in.)
Resistance/unit thickness	Rep/in.	= (in. Hg · ft² · h/gr)/in.

[b]Depending on construction and direction of vapor flow.

[c]Usually installed as vapor retarders, although sometimes used as exterior finish and elsewhere near cold side, where special considerations are then required for warm side barrier effectiveness.

[d]Dry-cup method.

[e]Wet-cup method.

[f]Other than dry- or wet-cup method.

[g]Low permeance sheets used as vapor retarders. High permeance used elsewhere in construction.

[h]Resistance and resistance/in. values have been calculated as the reciprocal of the permeance and permeability values.

[i]Cast at 10 mils wet film thickness.

5. k of a frozen soil may be higher or lower than that of the same unfrozen soil (because the conductivity of ice is higher than that of water but lower than that of the typical soil grains). Differences in k below moisture contents of 7 to 8% are quite small. At approximately 15% moisture content, differences in k-factors may vary up to 30% from unfrozen values.

When calculating annual energy use, values that represent typical site conditions as they vary during the year should be chosen. In climates where ground freezing is significant, accurate heat transfer simulations should include the effect of the latent heat of fusion of water. The energy released during this phase change significantly retards the progress of the frost front in moist soils.

Water Vapor Transmission Data for Building Components

Table 9 gives typical water vapor permeance and permeability values for common building materials. These values can be used to calculate water vapor flow through building components and assemblies using Equations (14) through (17) in Chapter 20.

Table 10 Typical Thermal Conductivity k for Industrial Insulations at Various Mean Temperatures—Design Values[a]

[a]Representative values for dry materials, which are intended as design (not specification) values for materials in normal use. Insulation materials in actual service may have thermal values that vary from design values depending on their in-situ properties (*e.g.*, density and moisture content). For properties of a particular product, use the value supplied by the manufacturer or by unbiased tests.

[b]These temperatures are generally accepted as maximum. When operating temperature approaches these limits, follow the manufacturers' recommendations.

[c]Some polyurethane foams are formed by means that produce a stable product (with respect to k), but most are blown with refrigerant and will change with time.

[d]See Table 4, footnote i.

[e]See Table 4, footnote j.

MECHANICAL AND INDUSTRIAL SYSTEMS

Thermal Transmission Data

Table 10 lists the thermal conductivities of various materials used as industrial insulations. These values are functions of the arithmetic mean of the temperatures of the inner and outer surfaces for each insulation.

Heat Loss from Pipes and Flat Surfaces

Tables 11A, 11B, and 12 give heat losses from bare steel pipes and flat surfaces and bare copper tubes. These tables were calculated using ASTM *Standard* C 680, Practice for Determination of Heat Gain or Loss and the Surface Temperature of Insulated Pipe and Equipment Systems by the Use of a Computer Program. User inputs for these programs include operating temperature, ambient temperature, pipe size, insulation type, number of insulation layers, and thickness for each layer. A program option allows the user to input a surface coefficient or surface emittance, surface orientation, and wind speed. The computer uses this information to calculate the heat flow and the surface temperature. The programs calculate the surface coefficients if the user has not already supplied them.

The equations used in ASTM C680 are:

$$h_{cv} = C\left(\frac{1}{d}\right)^{0.2}\left(\frac{1}{t_{avg}}\right)^{0.181}\Delta t^{0.266}\sqrt{1 + 1.277\,(\text{Wind})} \quad (4)$$

where

h_{cv} = convection surface coefficient, Btu/h · ft² · °F
d = diameter for cylinder, in. For flat surfaces and large cylinders ($d > 24$), use $d = 24$.
t_{avg} = average temperature of air film, °F
Δt = surface to air temperature difference, °F
Wind = air speed, mph
C = constant depending on shape and heat flow condition
= 1.016 for horizontal cylinders
= 1.235 for longer vertical cylinders
= 1.394 for vertical plates
= 1.79 for horizontal plates, warmer than air, facing upward
= 0.89 for horizontal plates, warmer than air, facing downward
= 0.89 for horizontal plates, cooler than air, facing upward
= 1.79 for horizontal plates, cooler than air, facing downward

$$h_{rad} = \frac{\epsilon \times 0.1713 \times 10^{-8}[(t_a + 459.6)^4 - (t_s + 459.6)^4]}{(t_a - t_s)} \quad (5)$$

where

h_{rad} = radiation surface coefficient, Btu/h · ft² · °F
ϵ = surface emittance
t_a = air temperature, °F
t_s = surface temperature, °F

[a]Calculations from ASTM C680-82; steel: k = 314.4 Btu · in/h · ft² · °F; ϵ = 0.94.

[b]Losses per square foot of pipe for pipes larger than 24 in. can be considered the same as losses per square foot for 24-in. pipe.

Example 7. Compute total annual heat loss from 165 ft of nominal 2-in. bare steel pipe in service 4000 h per year. The pipe is carrying steam at 10 psi and is exposed to an average air temperature of 80°F.

Solution: The pipe temperature is taken as the steam temperature, which is 239.4°F, obtained by interpolation from Steam Tables. By interpolation in Table 11A between 180°F and 280°F, heat loss from a 2-in. pipe is 285.3 Btu/h·ft. Total annual heat loss from the entire line is 285.3 Btu/h·ft × 165 ft × 4000 h = 188 million Btu.

In calculating heat flow, Equations (9) and (10) from Chapter 20 generally are used. For dimensions of standard pipe and fitting sizes, refer to the *Piping Handbook*. For insulation product dimensions, refer to ASTM *Standard* C 585, Recommended Practice for Inner and Outer Diameters of Rigid Thermal Insulation for Nominal Sizes of Pipe and Tubing (NPS) System, or to the insulation manufacturers' literature.

Examples 8 and 9 illustrate how Equations (9) and (10) from Chapter 20 can be used to determine heat loss from both flat and cylindrical surfaces. Figure 7 shows surface resistance as a function of heat transmission for both flat and cylindrical surfaces. The surface emittance is assumed to be 0.85 to 0.90 in still air at 80°F.

Example 8. Compute heat loss from a boiler wall if the interior insulation surface temperature is 1100°F and ambient still air temperature is 80°F. The wall is insulated with 4.5 in. of mineral fiber block and 0.5 in. of mineral fiber insulating and finishing cement.

Solution: Assume that the mean temperature of the mineral fiber block is 700°F, the mean temperature of the insulating cement is 200°F, and the surface resistance R_s is 0.60.

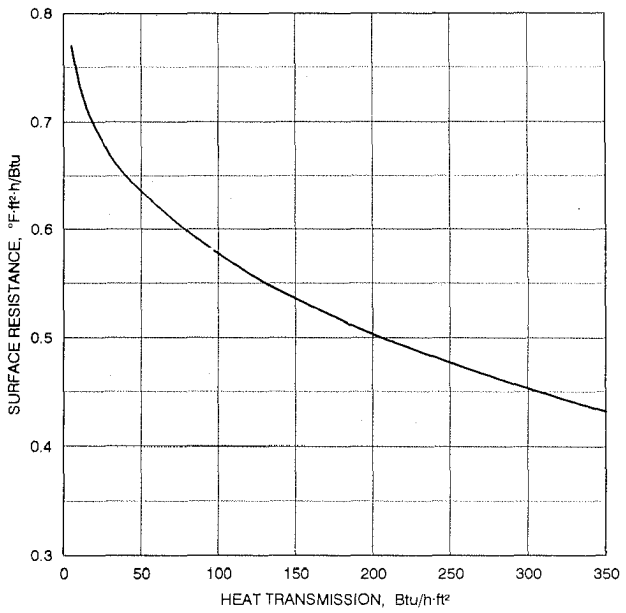

Fig. 7 Surface Resistance as Function of Heat Transmission for Flat Surfaces and Cylindrical Surfaces Greater than 24 Inches in Diameter

[a]Calculations from ASTM C680-82; for copper: k = 2784 Btu·in/h·ft²·°F.

From Table 10, $k_1 = 0.62$ and $k_2 = 0.80$. Using Equation (9) from Chapter 20:

$$q_s = \frac{1100 - 80}{(4.5/0.62) + (0.5/0.80) + 0.60} = \frac{1020}{8.48}$$
$$= 120.2 \text{ Btu/h} \cdot \text{ft}^2$$

As a check, from Figure 7, at 120.2 Btu/h · ft², $R_s = 0.56$. The mean temperature of the mineral fiber block is:

$$4.5/0.62 = 7.26; 7.26/2 = 3.63$$
$$1100 - [(3.63/8.48)(1020)] = 1100 - 437 = 663\,^\circ\text{F}$$

and the mean temperature of the insulating cement is:

$$0.5/0.80 = 0.63; 0.63/2 = 0.31; 7.26 + 0.31 = 7.57$$
$$1100 - [(7.57/8.48)(1020)] = 1100 - 911 = 189\,^\circ\text{F}$$

From Table 10, at 663 °F, $k_1 = 0.60$; at 189 °F, $k_2 = 0.79$.

Using these adjusted values to recalculate q_s:

$$q_s = \frac{1020}{(4.5/0.60) + (0.5/0.79) + 0.56} = \frac{1020}{8.69}$$
$$= 117.4 \text{ Btu/h} \cdot \text{ft}^2$$

From Figure 7, at 117.4 Btu/h · ft², $R_s = 0.56$. The mean temperature of the mineral fiber block is:

$$4.5/0.6 = 7.50; 7.50/2 = 3.75$$
$$1100 - [(3.75/8.69)(1020)] = 1100 - 440 = 660\,^\circ\text{F}$$

and the mean temperature of the insulating cement is:

$$0.5/0.79 = 0.63; 0.63/2 = 0.31; 7.50 + 0.31 = 7.81$$
$$1100 - [(7.81/8.69)(1020)] = 1100 - 917 = 183\,^\circ\text{F}$$

From Table 10, at 660 °F, $k_1 = 0.60$; at 183 °F, $k_2 = 0.79$.

Since R_s, k_1, and k_2 do not change at these values, $q_s = 117.4$ Btu/h · ft².

Example 9. Compute heat loss per square foot of outer surface of insulation if pipe temperature is 1200 °F and ambient still air temperature is 80 °F. The pipe is nominal 6-in. steel pipe, insulated with a nominal 3-in. thick diatomaceous silica as the inner layer and a nominal 2-in. thick calcium silicate as the outer layer.

Solution: From Chapter 42 of the 1992 ASHRAE *Handbook—Equipment*, $r_o = 3.31$ in. A nominal 3-in. thick diatomaceous silica insulation to fit a nominal 6-in. steel pipe is 3.02 in. thick. A nominal 2-in. thick calcium silicate insulation to fit over the 3.02-in. diatomaceous silica is 2.08 in. thick. Therefore, $r_i = 6.33$ in. and $r_s = 8.41$ in.

Assume that the mean temperature of the diatomaceous silica is 600 °F, the mean temperature of the calcium silicate is 250 °F and the surface resistance R_s is 0.50. From Table 10, $k_1 = 0.66$; $k_2 = 0.42$. By Equation (10) from Chapter 20:

$$q_s = \frac{1200 - 80}{[8.41 \ln (6.33/3.31)/0.66] + [8.41 \ln (8.41/6.33)/0.40] + 0.50}$$
$$= \frac{1120}{(5.45/0.66) + (2.39/0.40) + 0.50} = 76.0 \text{ Btu/h} \cdot \text{ft}^2$$

From Figure 7, at 76.0 Btu/h · ft², $R_s = 0.60$. The mean temperature of the diatomaceous silica is:

$$5.45/0.66 = 8.26; 8.26/2 = 4.13$$
$$1200 - [(4.13/14.83)(1120)] = 1200 - 312 = 888\,^\circ\text{F}$$

and the mean temperature of the calcium silicate is:

$$2.39/0.40 = 5.98; 5.98/2 = 2.99; 8.26 + 2.99 = 11.25$$
$$1200 - [(11.25/14.83)(1120)] = 1200 - 850 = 350\,^\circ\text{F}$$

From Table 10, $k_1 = 0.72$; $k_2 = 0.46$. Recalculating:

$$q_s = \frac{1120}{(5.45/0.72) + (2.39/0.46) + 0.60} = 83.8 \text{ Btu/h} \cdot \text{ft}^2$$

From Figure 7 at 83.8 Btu/h · ft², $R_s = 0.59$. The mean temperature of the diatomaceous silica is:

$$5.45/0.72 = 7.57; 7.57/2 = 3.78$$
$$1200 - [(3.78/13.36)(1120)] = 1200 - 317 = 883\,^\circ\text{F}$$

and the mean temperature of the calcium silicate is:

$$2.39/0.46 = 5.20; 5.20/2 = 2.60; 7.57 + 2.60 = 10.17$$
$$1200 - [(10.17/13.36)(1120)] = 1200 - 853 = 347\,^\circ\text{F}$$

From Table 10, $k_1 = 0.72$; $k_2 = 0.46$. Recalculating:

$$q_s = \frac{1120}{(5.45/0.72) + (2.39/0.46) + 0.59} = 83.8 \text{ Btu/h} \cdot \text{ft}^2$$

Since R_s, k_1, and k_2 do not change at 83.8 Btu/h · ft², this is q_s. The heat flow per ft² of the inner surface of the insulation is:

$$q_o = q_s (r_s/r_o) = 83.8(8.41/3.31) = 213 \text{ Btu/h} \cdot \text{ft}^2$$

Because trial and error techniques are tedious, the computer programs previously described should be used to estimate heat flows per unit area of flat surfaces or per unit length of piping, and interface temperatures including surface temperatures.

Several methods can be used to determine the most effective thickness of insulation for piping and equipment. Table 13 shows the recommended insulation thicknesses for three different pipe and equipment insulations. Installed cost data can be developed using procedures described by the Federal Energy Administration (1976). Computer programs capable of calculating thickness information are available from several sources. Also, manufacturers of insulations offer computerized analysis programs for designers and owners to evaluate insulation requirements. For more information on determining economic insulation thickness, see Chapter 20.

Chapters 3 and 20 give guidance concerning process control, personnel protection, condensation control, and economics. For specific information on sizes of commercially available pipe insulation, see ASTM *Standard* C585 and consult with the Thermal Insulation Manufacturers Association (TIMA) and its member companies.

CALCULATING HEAT FLOW FOR BURIED PIPELINES

In calculating heat flow to or from buried pipelines, the thermal properties of the soil must be assumed. Table 7 gives the apparent thermal conductivity values of various soil types, and Figure 6 shows the typical trends of apparent soil thermal conductivity with moisture content for various soil types. Table 8 provides ranges of apparent thermal conductivity for various types of rock. Kernsten (1949) also discusses thermal properties of soils. Carslaw and Jaeger (1959) give methods for calculating the heat flow taking place between one or more buried cylinders and the surroundings.

Consult manufacturer's literature for product temperature limitations. Table is based on typical operating conditions, *e.g.*, 65 °F ambient temperature and 7.5 mph wind speed, and may not represent actual conditions of use. Units for thickness, heat loss, and surface temperature are in inches, Btu/h · ft (Btu/h · ft^2 for flat surfaces), and °F, respectively.

CHAPTER 23

INFILTRATION AND VENTILATION

Types of Air Exchange 23.1
Ventilation and Thermal Loads 23.1
Ventilation and Indoor Air Quality 23.2
Driving Mechanisms 23.3
Airflow through Openings 23.7
Natural Ventilation Flow Rates 23.8
Infiltration 23.10
Air Exchange Measurement 23.10
Air Leakage 23.12
Controlling Air Leakage 23.16
Residential Ventilation Systems 23.17
Calculating Air Exchange 23.18

OUTDOOR air that flows through a building either intentionally as ventilation air or unintentionally as infiltration (and exfiltration) is important for two reasons. Outdoor air is often used to dilute indoor air contaminants, and the energy associated with heating or cooling this outdoor air is a significant space-conditioning load. The magnitude of these airflow rates should be known at maximum load to properly size equipment and at average conditions, to properly estimate average or seasonal energy consumption. Minimum air exchange rates need to be known to assure proper control of indoor contaminant levels. In large buildings, the effect of infiltration and ventilation on distribution and interzone airflow patterns, which include smoke circulation patterns in the event of fire, should be determined (see Chapter 47 of the 1991 ASHRAE *Handbook—Applications*).

Air exchange between indoors and out is divided into ventilation (intentionally controlled) and infiltration (unintentional and uncontrolled). Ventilation can be natural and forced. Natural ventilation is unpowered airflow through open windows, doors, and other intentional openings in the building envelope. Forced ventilation is intentional, powered air exchange by a fan or blower and intake and/or exhaust vents that are specifically designed and installed for ventilation.

Infiltration is uncontrolled airflow through cracks, interstices, and other unintentional openings. Infiltration, exfiltration, and natural ventilation airflows are caused by pressure differences due to wind, indoor-outdoor temperature differences, and appliance operation.

This chapter focuses on residences and small commercial buildings in which air exchange is due primarily to envelope or shell infiltration. The physical principles are also discussed in relation to large buildings in which air exchange depends more on mechanical ventilation than it does on building envelope performance.

TYPES OF AIR EXCHANGE

Buildings have three different modes of air exchange: (1) forced ventilation, (2) natural ventilation, and (3) infiltration. These modes differ significantly in how they affect energy, air quality, and thermal comfort. They also differ in their ability to maintain over time a desired air exchange rate. The air exchange rate in a building at any given time generally includes all three modes, and they all must be considered even when only one is expected to dominate.

Forced ventilation affords the greatest potential for control of air exchange rate and air distribution within a building through the proper design, installation, operation, and maintenance of the ventilation system. Forced or mechanical ventilation equipment and systems are described in Chapers 1, 2, and 9 of the 1992 ASHRAE *Handbook—Systems and Equipment*. An ideal forced ventilation system has a sufficient ventilation rate to control indoor contaminant levels and, at the same time, avoids overventilation and the associated energy penalty. In addition, it maintains good thermal comfort (see Chapters 8 and 32).

Forced ventilation is generally mandatory in larger buildings, where a minimum amount of outdoor air is required for occupant health and comfort, and where a mechanical exhaust system is advisable or necessary. Forced ventilation has generally not been used in residential and other envelope-dominated structures. However, tighter, more energy-conserving buildings require ventilation systems to assure an adequate amount of outdoor air for maintaining acceptable indoor air quality.

Natural ventilation through intentional openings is caused by pressures from wind and/or indoor-outdoor temperature differences. Airflow through open windows and doors and other design openings can be used to provide adequate ventilation for contaminant dilution and temperature control. Unintentional openings in the building envelope and the associated infiltration can interfere with desired natural ventilation air distribution patterns and lead to larger than design airflow rates. Natural ventilation is sometimes defined to include infiltration, but in this chapter it does not.

Infiltration is the uncontrolled flow of air through unintentional openings driven by wind, temperature difference, and/or appliance-induced presures across the building envelope. Infiltration is least reliable in providing adequate ventilation and distribution, because it depends on weather conditions and the location of unintentional openings. It is the main source of ventilation in envelope-dominated buildings and is also an important factor in mechanically ventilated buildings.

VENTILATION AND THERMAL LOADS

Outdoor air introduced into a building constitutes part of the space-conditioning (heating, cooling, dehumidification) load, which is one reason to limit air exchange rates in buildings to the minimum required. Air exchange typically represents 20 to 40% of the shell-dominated building's thermal load. Chapters 25 and 26 cover thermal loads in more detail.

Air exchange increases a building's thermal load in three ways. First, the incoming air must be heated or cooled from the outdoor air temperature to the indoor air temperature. The rate of energy consumption due to this sensible heating or cooling is given by:

$$q_s = 60\, Q\, \rho\, c_p\, \Delta t \qquad (1)$$

where

q_s = sensible heat load, Btu/h
Q = airflow rate, cfm
ρ = air density, lb_m/ft^3 (about 0.075)
c_p = specific heat of air, Btu/lb · °F (about 0.24)
Δt = indoor-outdoor temperature difference, °F

The preparation of this chapter is assigned to TC 4.3, Ventilation Requirements and Infiltration.

Second, air exchange modifies the moisture content of the air in a building. This is particularly important in the summer in some locations when the humid outdoor air must be dehumidified. In the winter, when the humidity ratio of the indoor air is much lower than that of the outside air, humidification may be needed. The rate of energy consumption associated with these latent loads is given by:

$$q_l = 60\, Q\, \rho\, h_{fg}\, \Delta W \quad (2)$$

where

q_l = latent heat loads, Btu/h
h_{fg} = latent heat of vapor at appropriate air temperature, Btu/lb_m (about 1000)
ΔW = humidity ratio of indoor air minus humidity ratio of outdoor air, lb_m water/lb_m dry air

Finally, air exchange can increase a building's thermal loads by decreasing the performance of the envelope insulation system. Air flowing around and through the insulation can increase heat transfer rates above design rates. The effect of such airflow on insulation system performance is difficult to quantify but should be considered. Airflow within the insulation system can also decrease the system's performance due to moisture condensing in and on the insulation.

VENTILATION AND INDOOR AIR QUALITY

Outdoor air requirements for acceptable indoor air quality (IAQ) have long been debated, and different rationales have produced radically different ventilation standards (Grimsrud and Teichman 1989; Janssen 1989; Klauss *et al.* 1970; Yaglou *et al.* 1936, 1937). Historically, the major considerations have included the amount of outdoor air required to control moisture, carbon dioxide (CO_2), odors, and tobacco smoke generated by occupants. These considerations have led to prescriptions of the minimum rate of outside air supply per occupant. More recently, the maintenance of acceptable indoor concentrations of a variety of additional pollutants that are not generated primarily by occupants has been a major concern. The most common pollutants of concern and their sources are presented in Table 1. Additional information on contaminants can be found in Chapter 11; odors are covered in Chapter 12.

Table 1 Indoor Air Pollutants and Sources

Sources	Pollutant Types
OUTDOOR	
Ambient air	SO_2, NO, NO_2, O_3, hydrocarbons, CO, particulates, bioaerosols
Motor vehicles	CO, Pb, hydrocarbons, particulates
Soil	Radon, organics
INDOOR	
Building construction materials	
Concrete, stone	Radon
Particleboard, plywood	Formaldehyde
Insulation	Formaldehyde, fiberglass
Fire retardant	Asbestos
Adhesives	Organics
Paint	Mercury, organics
Building contents	
Heating and cooking combustion appliances	CO, NO, NO_2, formaldehyde, particulates, organics
Furnishings	Organics
Water service; natural gas	Radon
Human occupants	
Metabolic activity	H_2O, CO_2, NH_3, odors
Human activities	
Tobacco smoke	CO, NO_2, organics, particulates, odors
Aerosol spray devices	Fluorocarbons, vinyl chloride, organics
Cleaning and cooking products	Organics, NH_3, odors
Hobbies and crafts	Organics
Damp organic materials, stagnant water Coil drain pans Humidifiers	Bioaerosols

Indoor pollutant concentrations depend on the strength of pollutant sources and the total rate of pollutant removal. Pollutant sources include the outdoor air; indoor sources such as occupants, furnishings, and appliances; and the soil adjacent to the building. Pollutant removal processes include ventilation with outside air, local exhaust ventilation, deposition on surfaces, chemical reactions, and air cleaning processes. If general building ventilation is the only significant pollutant removal process, the indoor air is thoroughly mixed, and the pollutant source strength and ventilation rate have been stable for a sufficient period; the steady-state indoor pollutant concentration is given by the equation

$$C_i = C_o + S/Q \quad (3)$$

where

C_i = steady-state indoor concentration
C_o = outdoor concentration
S = total pollutant source strength
Q = ventilation rate (outdoor air only)

Variations in pollutant source strengths between buildings (and not variation in ventilation rates) is considered the largest cause of the building-to-building variation in the concentrations of pollutants that are not generated by occupants. Turk *et al.* (1989) found that a lack of correlation between average indoor respirable particle concentrations and whole building outdoor ventilation rates indicated that source strength, high outdoor concentrations, building volumes, and other removal processes are important. Because pollutant source strengths are highly variable, maintenance of minimum ventilation rates does not ensure acceptable indoor air quality in all situations. The lack of health-based concentration standards for many indoor air pollutants, primarily because of the lack of health data, makes the specification of minimum ventilation rates even more difficult.

Regardless of the complexities and uncertainties described previously, building designers and operators require guidance on ventilation and indoor air quality.

ASHRAE *Standard* 62-1989 provides guidance on ventilation and indoor air quality in the form of two alternative procedures. In the *ventilation rate procedure*, indoor air quality is assumed to be acceptable if the concentrations of six pollutants in the incoming outdoor air meet the United States national ambient air quality standards and the outside air supply rates meet or exceed values (which vary depending on the type of space) provided in a table. The minimum outside air supply per person for any type of space is 15 cfm. This minimum rate will maintain indoor CO_2 concentrations below 0.1% (1000 parts per million) assuming a typical CO_2 generation rate per occupant (Janssen 1989). This minimum outside air supply rate was based, in part, on research by Berg-Munch *et al.* (1986), which indicated that 15 cfm was required to satisfy the odor perceptions of 80% or more of visitors.

The second alternative in *Standard* 62-1989 is the *indoor air quality procedure*. Under this procedure, any outside air supply rates are acceptable if the indoor concentrations of nine pollutants are maintained below specified values and the air is deemed acceptable via subjective evaluations of odor. If users of the IAQ procedure control pollutant source strengths or use air cleaning or local exhaust ventilation, they may be able to reduce the outside air supply rates below the rates specified in the ventilation rate procedure. Modest energy savings may result as described by Eto and Meyer (1988) and Eto (1990). However, the maximum acceptable CO_2 concentrations of 0.1% in the IAQ procedure effec-

tively limits the minimum ventilation rate to 15 cfm per occupant, unless CO_2 is removed by air cleaning, which is generally considered impractical.

In cases of large contaminant source strengths, impractically high levels of ventilation are required to control contaminant levels, and other methods of control are more effective. Removal or reduction of contaminant sources is a very effective means of control. Spot ventilation, such as range hoods or bathroom exhausts, for controlling a localized source is also effective.

Particles can be removed with various types of air filters. Gaseous contaminants with higher molecular weight can be controlled with activated carbon or alumina pellets impregnated with substances such as potassium permanganate. Chapter 25 of the 1992 ASHRAE *Handbook—Systems and Equipment* has information on air cleaning.

Source control and local exhaust, as opposed to dilution with ventilation air, is the method of choice in industrial environments. Indoor air quality problems and methods of control are covered in the proceedings of annual IAQ conferences sponsored by ASHRAE (1986 through 1992). Industrial ventilation is discussed in Chapters 25 and 27 of the 1991 ASHRAE *Handbook—Applications* and in *Industrial Ventilation: A Manual of Ventilation Practice* (ACGIH 1991).

DRIVING MECHANISMS

Natural ventilation and infiltration are driven by pressure differences across the building envelope caused by wind, air density differences due to temperature differences between indoor and outdoor air (stack effect), and the operation of appliances, such as combustion devices, leaky forced-air thermal distribution systems, and mechanical ventilation systems. The pressure difference at a location depends on the magnitude of these driving mechanisms as well as on the characteristics of the openings in the building envelope, *i.e.*, their locations and the relationship between pressure difference and airflow for each opening.

Pressure differences across the building envelope are based on the requirement that the mass flow of air into the building equals the mass flow out. In general, density differences between indoors and outdoors can be neglected, so the volumetric airflow rate into the building equals the volumetric airflow rate out. Based on this assumption, the envelope pressure differences can be determined; however, such a determination requires a great deal of detailed information that is essentially impossible to obtain.

When wind impinges on a building, it creates a distribution of static pressures on the building's exterior surface, which depends on the wind direction and the location on the building exterior. This pressure distribution is independent of the pressure inside the building p_i. If (1) no other forces act on the building, (2) no indoor-outdoor temperature difference exists, and (3) no appliance forces air through the building, the pressure differences are determined by the interior static pressure, according to:

$$\Delta p = p_o + p_w - p_i \tag{4}$$

where

Δp = pressure difference between outdoors and indoors at location
p_o = static pressure at reference height in undisturbed flow
p_w = wind pressure at location
p_i = interior pressure at height of location

If no indoor-outdoor temperature difference exists, the interior static pressure p_i decreases linearly with height at a rate dependent on the interior temperature. This rate of pressure decrease equals $-\rho_i g$, where ρ_i is the average interior air density and g is the acceleration of gravity. The interior static pressure equilibrates to a value such that the total airflow into the building equals the total airflow out of the building. The interior static pressure may be determined by calculating the airflow through each opening as a function of the interior pressure, adding all of these airflow rates together, setting this sum equal to zero, and solving for the interior pressure. However, to solve for the interior pressure in this way, the location of each opening in the building envelope, the value of p_w at each opening, and the relationship between airflow rate and pressure difference for each opening must be known.

When an indoor-outdoor temperature difference exists, it imposes a gradient in the pressure difference. This pressure difference Δp_s is a function of height and temperature difference and may be added to the pressure difference due to wind in Equation (4). The pressure difference is now expressed as:

$$\Delta p = p_o + p_w - p_{i,r} + \Delta p_s \tag{5}$$

The parameter $p_{i,r}$ is the interior static pressure at some reference height, and this pressure again assumes a value such that the total inflow equals the total outflow. A summation of all the airflows through these openings can be set up, set equal to zero, and solved for the interior pressure at the reference height.

When an appliance such as a combustion device, leaky forced-air distribution system, or a ventilation fan operates, an additional airflow is imposed on the building. The pressure difference is still calculated using Equation (5), but the interior pressure $p_{i,r}$ changes so that the balance between inflow and outflow is maintained. This balance necessarily includes the airflow rate(s) associated with the appliance(s).

To determine the pressure differences across the building envelope and the corresponding air exchange rates, building-specific information about the exterior pressure distribution due to wind and the location and airflow rate/pressure difference relationship for every opening in the building envelope are needed. These inputs are difficult to obtain for any given building, making such a determination unrealistic.

Wind Pressure

Wind pressures are generally positive with respect to the static pressure in the undisturbed airstream on the windward side of a building and negative on the leeward side. Pressures on the other sides are negative or positive, depending on wind angle and building shape. Static pressures over building surfaces are almost proportional to the velocity head of the undisturbed airstream. The wind pressure or velocity head is given by Bernoulli's equation, assuming no height change or head losses:

$$p_v = C_1 C_p \rho v^2/2 \tag{6}$$

where

p_v = surface pressure relative to static pressure in undisturbed flow, in. of water
ρ = air density, lb_m/ft^3 (about 0.075)
v = wind speed, mph
C_p = surface pressure coefficient, dimensionless
C_1 = unit conversion factor = 0.0129

Therefore, Equation (5) can be rewritten as:

$$\Delta p = p_o + C_1 C_p \rho v^2/2 - p_i \tag{7}$$

C_p is a function of location on the building envelope and wind direction. Chapter 14 provides additional information on the values of C_p. Although standard conditions are frequently used, the air density and, consequently, the wind pressure can vary for a given wind speed with changes in temperature and/or elevation.

For example, for an elevation rise from sea level to 5000 ft, or an air temperature change from −20 to 70°F, the air density will drop about 20%. If these elevation and temperature changes occur simultaneously, the air density will drop by about 45%. Therefore, the effects of local air density cannot be ignored.

The wind speed incident on a building is generally lower than the average meteorological wind speed for a region; thus, meteorological data usually overestimates wind pressures on a building. Building wind speeds are lower because of the effects of height, terrain, and shielding (Lee *et al.* 1980). The wind speed is zero at the ground surface and increases with height up to an altitude of about 2000 ft above ground level. Meteorological measurements typically are made at a height of 33 ft in open areas. Residential building heights are generally less than 33 ft and are therefore subject to lower wind pressures. Tall buildings are subject to a range in wind speed over the height of the building, exposing the exterior to wind pressures that are both lower and higher than estimates based on Equation (6).

A database of surface pressure coefficients from eight investigators for low-rise buildings and one source for high-rise buildings was developed by Swami and Chandra (1988). The 544 average surface pressure coefficients from the database were used to develop a relationship (with a correlation coefficient 0.80) between wind incident angle, building side ratio, and average surface pressure coefficient:

$$NC_p = \ln [1.248 - 0.703 \sin (a/2) - 1.175 \sin^2 (a) + 0.131 \sin^3 (2aG) + 0.769 \cos (a/2) + 0.07 G^2 \sin^2 (a/2) + 0.717 \cos^2 (a/2)] \quad (8)$$

where

NC_p = normalized C_p
a = angle in degrees between wind direction and outward normal of wall under consideration
G = natural log of ratio of width of wall under consideration to width of adjacent wall

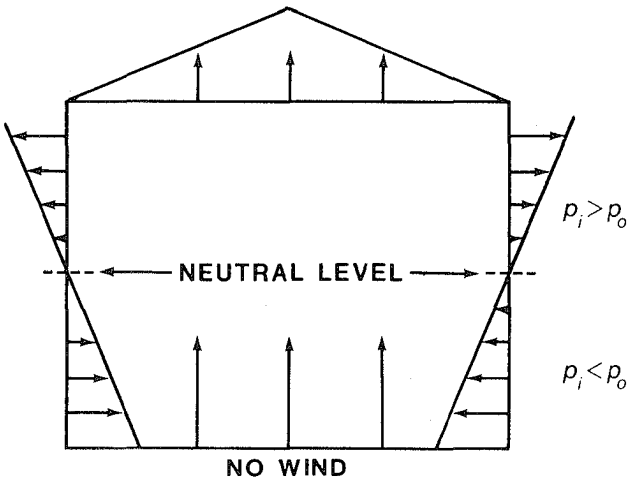
They further noted that the uncertainties in the estimation of site wind speed and the effect of surrounding buildings are likely to be equal to or greater than the uncertainty in estimating C_p from the correlations.

The shielding effects of trees, shrubbery, and other buildings, within several building heights of a particular building, produce large-scale turbulence that not only reduces effective wind speed but also alters wind direction. Thus, meteorological wind speed data must be reduced carefully when applied to low buildings. Chapter 14 provides additional guidance on estimating wind pressures.

The magnitude of the pressure differences found on the surfaces of buildings varies rapidly with time because of turbulent fluctuations in the wind (Grimsrud *et al.* 1979, Etheridge and Nolan 1979). However, the use of average wind pressures to calculate pressure differences is usually sufficient to calculate average infiltration values. In residential buildings, the magnitude of wind pressure differences averaged over 20 min seldom exceeds ±0.02 in. of water under typical conditions. In many cases, the averages are less than ±0.01 in. of water. For tall buildings or buildings completely exposed to open terrain, the pressure on the windward side is much closer to those calculated from average wind speeds for the site (Tamura and Wilson 1968). In the latter cases, for example, if v = 6.7 mph, $p_v \cong$ 0.02 in. of water; if v = 15.7 mph, $p_v \cong$ 0.12 in. of water (assuming C_p = 1).

Stack Pressures

Temperature differences between indoors and outdoors cause density differences, and therefore pressure differences, that drive infiltration. During the heating season, the warmer inside air rises and flows out of the building near its top. It is replaced by colder outdoor air that enters the building near its base. During the cooling season, the flow directions are reversed and generally lower, because the indoor-outdoor temperature differences are smaller. Qualitatively, the pressure distribution over the building in the heating season due to the stack effect takes the form shown in Figure 1.



Note: Arrows indicate magnitude and direction of pressure difference.

Fig. 1 Pressure Differences Caused by Stack Effect for Typical Structure (Heating)

The height at which the interior and exterior pressures are equal is called the neutral pressure level (NPL) (Tamura and Wilson 1966, 1967a). Above this point (during the heating season), the interior pressure is greater than the exterior; below this point, the greater exterior pressure causes airflow into the building.

The pressure difference due to the stack effect at height h is:

$$\Delta p_s = C_2 (\rho_o - \rho_i) g (h - h_{NPL}) = C_2 \rho_i g (h - h_{NPL})(T_i - T_o)/T_o \quad (9)$$

where

Δp_s = pressure difference due to stack effect, in. of water
ρ = air density, lb_m/ft^3 (about 0.075 for indoor conditions)
g = gravitational constant, 32.2 ft/s^2
h = height of observation, ft
h_{NPL} = height of neutral pressure level, ft
T = average absolute temperature, °R
C_2 = unit conversion factor = 0.00598

Subscripts

i = inside
o = outside

Chastain and Colliver (1989) show that the average of the vertical distribution of temperature differences due to stratification rather than the localized temperature difference near the opening is the appropriate temperature difference to use in this equation.

A useful estimate of the magnitude of the stack effect on a building is that the pressure difference induced by the stack effect is 2.7 × 10^{-5} in. of water/$ft^2 \cdot$°R. This estimate neglects any resistance to airflow within the structure. Therefore, in a one-story house with an 8-ft ceiling, an NPL of one-half the building height, and a temperature difference of 45°R, the stack pressure will be 0.005 in. of water at the ceiling and floor. In a tall building (*e.g.*, 20 stories of 13 ft each) with no internal resistance to airflow, the stack pressure under these same conditions will be 0.18 in. of water. For cold climate conditions, these values are significantly greater due to the increased outdoor air density.

The location of the NPL at zero wind speed is a structure-dependent parameter that depends only on the vertical distribution of openings in the shell, the resistance of the openings to airflow, and the resistance to vertical airflow within the building. If the openings are uniformly distributed vertically, they have the same resistance to airflow, and there is no internal airflow resistance, the NPL is at the midheight of the building (Figure 1). If there is only one opening or an extremely large opening relative to any others, the NPL is at or near the center of this opening. Foster and Down (1987) studied the location of the NPL as it relates to natural ventilation in a building with only two openings. Lee *et al.* (1985) studied, both experimentally and analytically, the characteristics of thermal performance of high-rise buildings using an idealized model building with a number of openings at various locations and temperature distributions. Later Lee *et al.* (1988) showed that the ratio of floor opening area to exterior opening areas had a dominant role on pressure distribution. Chastain and Colliver (1989) investigated the location of the NPL in walls with multiple openings and found that it was independent of the temperature difference and that the resulting mean density difference across the building envelope should be used.

Internal partitions, stairwells, elevator shafts, utility ducts, chimneys, vents, and mechanical supply and exhaust systems complicate the analysis of NPL locations. Chimneys and openings at or above roof height raise the NPL in small buildings. Exhaust systems increase the height of the NPL; outdoor air supply systems lower it.

Available data on the NPL in various kinds of buildings is limited. The NPL in tall buildings varies from 0.3 to 0.7 of total building height (Tamura and Wilson 1966, 1967a). For houses, especially those with chimneys, the NPL is usually above midheight. Operating a combustion heat source with a flue raises the NPL further, sometimes above the ceiling (Shaw and Brown 1982).

Equation (9) provides a maximum stack pressure difference, given no internal airflow resistance. The sum of the pressure differences across the exterior wall at the bottom and top of the building, as calculated by Equation (9), equals the total theoretical draft for the building. The sum of the actual top and bottom pressure differences, divided by the total theoretical draft, equals the *thermal draft coefficient.* The value of the thermal draft coefficient depends on the airflow resistance of the exterior walls relative to the airflow resistance between floors. For a building without internal partitions, the total theoretical draft is achieved across the exterior walls (Figure 2A), and the thermal draft coefficient equals 1. In a building with airtight separations at each floor, each story acts independently, its own stack effect being unaffected by that of any other floor (Figure 2B). The ratio of the actual to the theoretical draft is minimized in this case.

Real multistory buildings are neither open inside (Figure 2A), nor airtight between stories (Figure 2B). Vertical air passages, stairwells, elevators, and other service shafts allow airflow between floors. Figure 2C represents a heated building with uniform openings in the exterior wall, through each floor, and into the vertical shaft at each story. Between floors, the slope of the line representing the inside pressure is the same as that shown in Figure 2A, and the discontinuity at each floor (Figure 2B) represents the pressure difference across it. Total stack effect for the building remains the same, but some of the total pressure difference maintains flow through openings in the floors and vertical shafts. As a result, the pressure difference across the exterior wall at any level is less than it would be with no internal flow resistance.

Maintaining airtightness between floors and from floors to vertical shafts is a means of controlling indoor-outdoor pressure differences, and therefore infiltration. Good separation is also conducive to the proper operation of mechancial ventilation and smoke control systems. Tamura and Wilson (1967b) showed that when vertical shaft leakage is at least two times the envelope leakage, the thermal draft coefficient is almost 1. Openings in floors are less effective in providing communication between floors; as the building height increases, they become even less effective. Measurements of pressure differences in three tall office buildings by Tamura and Wilson (1967a) indicated that the thermal draft coefficient ranged from 0.8 to 0.9 with the ventilation systems off.

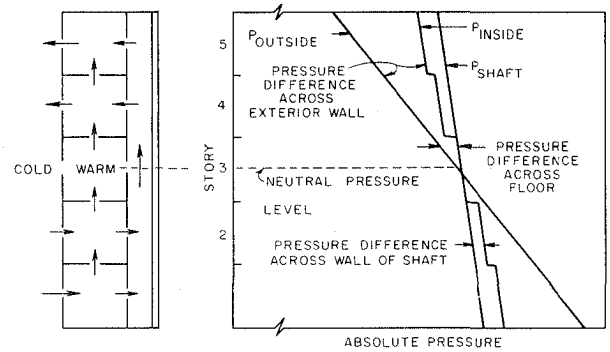

Fig. 2C Stack Effect for an Idealized Building

Mechanical Systems

The operation of mechanical equipment, such as ventilation/exhaust systems and vented combustion devices, affects pressure differences across the building envelope. The interior static pressure adjusts such that the airflows through all the openings in the building envelope plus equipment-induced airflows balance to zero. These changes in pressure differences and airflow rates caused by mechanical equipment are unpredictable, unless the location of each opening in the envelope and the relationship between pressure difference and airflow rate for each opening are known. The interaction of mechanical ventilation system operation and envelope airtightness has been discussed for low-rise buildings (Nylund 1980) and for office buildings (Tamura and Wilson 1966, 1967b; Persily and Grot 1985a).

Air exhausted from a building must be balanced by increasing the airflow into the building through other openings. The airflow at some locations changes from outflow to inflow because in the winter (summer), the NPL rises (falls). For supply fans, the situation is reversed, and envelope inflows become outflows. Thus, the effects a mechanical system has on a building must be considered. Depressurization caused by an improperly designed system can increase radon entry rates into a building and interfere with the proper operation of combustion device venting or other exhaust systems. Overpressurization can force moist indoor air through the building envelope and, in cold climates, moisture may condense within the building envelope.

The interaction between mechanical systems and the building envelope also holds for systems serving zones of buildings. The performance of zone-specific exhaust or pressurization systems is affected by the leakage in zone partitions, as well as in exterior walls.

Mechanical systems can also create infiltration-driving forces in single-zone buildings. Specifically, a large fraction of single-family houses with central forced-air duct systems have multiple supply registers, yet only a central return register. In these houses, when internal doors are closed, large positive indoor-outdoor pressure differentials are created for rooms with only supply registers, whereas the return duct tends to depressurize relative to outside. This is caused by the resistance of internal door undercuts to flow from the supply register to the return (Modera *et al.* 1991). The magnitudes of the indoor-outdoor pressure differentials created have been measured to average 0.012 to 0.024 in. of water (Modera *et al.* 1991).

Building envelope airtightness and interzone airflow resistance can also affect the performance of mechanical systems. The actual airflow rate delivered by these systems, particularly ventilation systems, depends on the pressure they work against. This effect is the same as the interaction of a fan with its associated duct work discussed in Chapter 32 of this volume and in Chapter 18 in the 1992 ASHRAE *Handbook—Systems and Equipment*. The building envelope and its leakage can be considered part of the duct work in determining the pressure drop of the system.

Combining Driving Forces

The pressure differences just discussed are considered in combination by adding them together and determining the airflow rate through each opening due to this total pressure difference. Because the airflow rate through these openings is not linearly related to pressure difference, the driving forces must be combined in this manner, as opposed to adding the airflow rates due to the separate driving forces.

Figure 3 qualitatively shows the addition of driving forces for a building with uniform openings above and below midheight and without significant internal resistance to airflow. The slopes of the pressure lines are functions of the densities of the indoor and outdoor air. In Figure 3A, with inside air warmer than outside and pressure differences caused solely by thermal forces, the NPL is at midheight, with inflow through lower openings and outflow through higher openings. (Direction of flow is always from the higher to the lower pressure region.) A chimney or mechanical exhaust decreases the inside pressure and thus shifts the inside pressure line to the left, raising the NPL; an excess of outdoor supply air over exhaust would lower it. Figure 3B presents qualitative uniform pressure differences caused by wind alone, with the effect on windward and leeward sides equal but opposite. When the temperature difference and wind effects both exist, the pressures due to each are added together to determine the total pressure difference across the building envelope. Figure 3C shows the combination where the wind force of Figure 3B has just balanced the thermal force of Figure 3A, causing no pressure difference at the top windward or bottom leeward side. Total airflow is similar to that with the wind acting alone, but significantly larger than the airflow due only to the stack effect.

The relative importance of the wind and stack pressures in a building depends on building height, internal resistance to vertical airflow, location and flow resistance characteristics of envelope openings, local terrain, and the immediate shielding of the building. The taller the building and the less the internal resistance to airflow, the stronger the stack effect. The more exposed a building, the more susceptible it will be to wind. For any building, there will be ranges of wind speed and temperature difference for which the building's infiltration is dominated by the stack effect, the wind, or a regime in which the driving pressures of both must be considered (Sinden 1978). These factors determine, for specific values of temperature difference and wind speed, in which regime the building's infiltration lies.

The effect of mechanical ventilation on envelope pressure differences is more complex and depends on the direction of the ventilation flow (exhaust or supply) and differences in these ventilation flows among the zones of the building. If mechanically supplied outdoor air is provided uniformly to each story, the change in the exterior wall pressure difference pattern from ther-

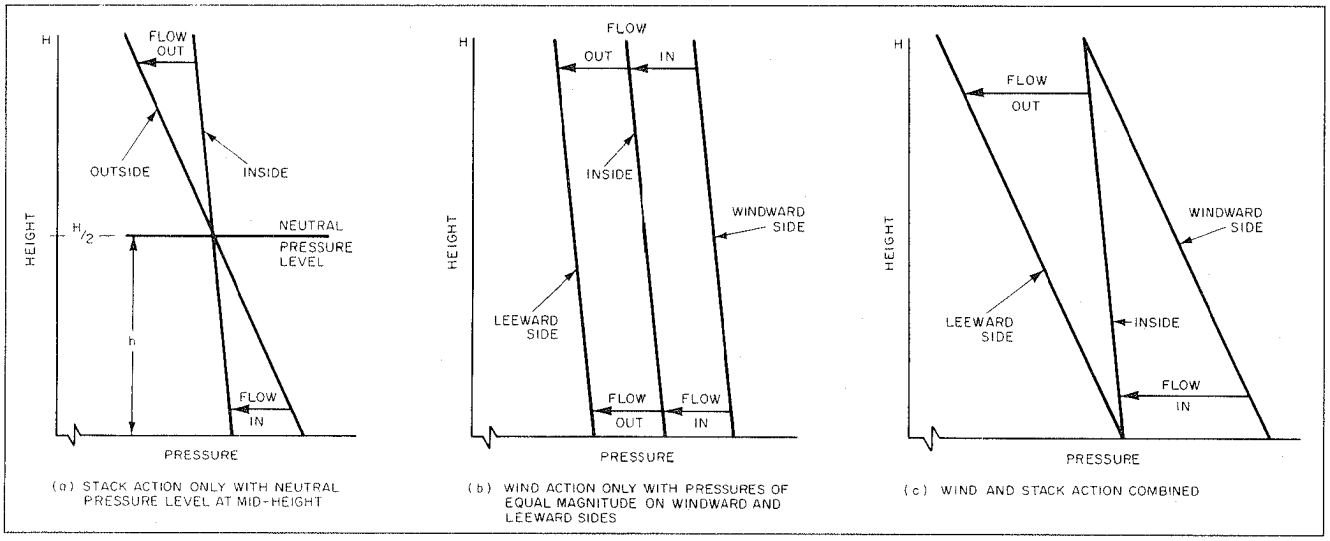

Fig. 3 Distribution of Inside and Outside Pressures over Height of Building

mal pressures is uniform. With a nonuniform supply of outdoor air (for example, to one story only), the extent of pressurization varies from story to story and depends on the internal airflow resistance. Pressurizing all levels uniformly has little effect on the pressure differences across floors and vertical shaft enclosures, but pressurizing individual stories increases the pressure drop across these internal separations. Pressurization of the ground level is often used in tall buildings to reduce the stack pressures across entries.

The pressure fields illustrated in Figure 3 indicate that the wind and stack effects can be combined by simply adding the pressures. Because this pressure addition can cause direction changes in the resulting flow, the flows cannot be combined as simply. An accurate superposition of the two effects requires detailed knowledge of the two pressure fields. Several theoretical models and measurements have been made for combining forced and natural ventilation (Kiel and Wilson 1987, Persily and Norford 1987, Shaw 1987). A simpler model (Sherman 1992) uses the neutral level and wind direction to combine the two effects. For typical buildings, the following equation can be used to combine the stack and wind effects:

$$Q_{ws} = (Q_w^2 + Q_s^2)^{0.5} \tag{10}$$

where

Q_{ws} = infiltration from both wind and stack effects, cfm
Q_w = infiltration from wind, cfm
Q_s = infiltration from stack effect, cfm

Mechanical ventilation can change the flow through the envelope by affecting the internal pressure. When both supply and exhaust fans are present, the mechanical ventilation can be broken up into the amount of ventilation flow which creates no change in pressure distribution or the "balanced" part:

$$Q_{bal} = \text{minimum of } (Q_{supply}, Q_{exhaust}) \tag{11}$$

and an "unbalanced" part:

$$Q_{unbal} = \text{maximum of } (Q_{supply}, Q_{exhaust}) - Q_{bal} \tag{12}$$

(If the building has only supply or exhaust, all the flow is unbalanced.)

Because the balanced part of the flow does not affect the pressure distribution across the envelope, it adds simply to the wind- and stack-driven pressures. The unbalanced part, however, does affect the pressure distribution and, therefore, only part of it contributes to additional ventilation (Sherman 1992) until the fan completely dominates. The efficiency of unbalanced ventilation depends again on the neutral level and wind direction, but it can be assumed to be 50% for typical cases.

The total ventilation then becomes the following:

$$Q = Q_{bal} + \text{Maximum } (Q_{unbal}, Q_{ws} + 0.5\,Q_{unbal}) \tag{13}$$

Levins (1982) and Kiel and Wilson (1987) further discuss the combination of mechanical ventilation airflow rates with naturally induced infiltration rates.

Shaw and Brown (1982) compared air infiltration in identical homes, with and without a gas furnace with a chimney. Figure 4 presents the effects of exfiltration through the chimney and ceiling with and without the gas furnace; it also shows the impact of the chimney on the NPL.

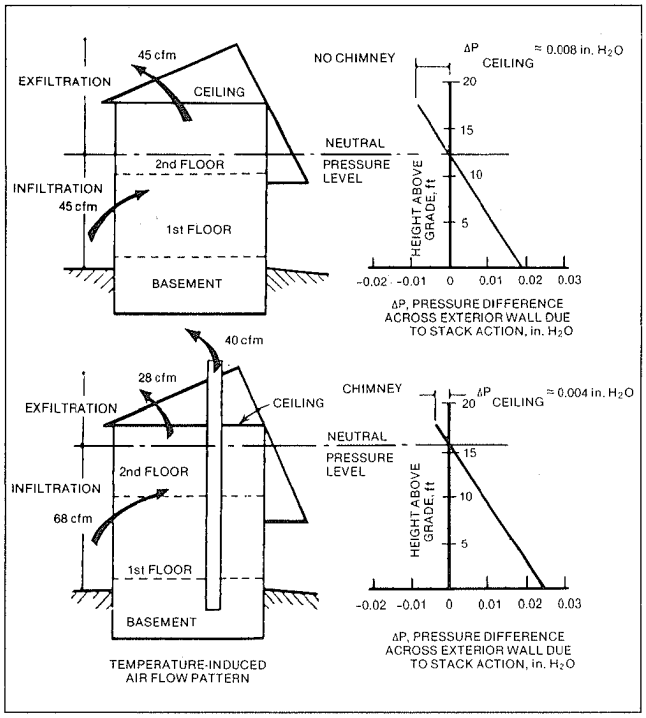

Fig. 4 Temperature-Induced Pressure and Airflow Patterns under Operation of Electric or Gas Furnace for Δt = 50 °F

AIRFLOW THROUGH OPENINGS

The relationship between the airflow through an opening in the building envelope Q and the pressure difference Δp across it is called the leakage function of the opening. The form of the leakage function depends on the geometry of the opening. Background theoretical material relevant to leakage functions may be found in Chapter 2, Hopkins and Hansford (1974), Etheridge (1977), Kronvall (1980a), and Chastain *et al.* (1987).

The relationship describing the airflow through an opening is based on the solution to the Navier-Stokes equation for the idealized case of infinite parallel plates with several simplifying assumptions such as steady, fully developed laminar flow. The most commonly used expression for the airflow rate through an opening is:

$$Q = C_3 C_D A \sqrt{2\,\Delta p/\rho} \tag{14}$$

where

Q = airflow rate, cfm
C_D = discharge coefficient for opening, dimensionless
A = cross-sectional area of opening, ft²
ρ = air density, lb/ft³
Δp = pressure difference across opening, in. of water
C_3 = conversion factor = 776

The discharge coefficient C_D is a dimensionless number that depends on the opening geometry and the Reynolds number of the flow.

Airflow through constant area ducts is well characterized. At sufficiently low Reynolds numbers, the fluid velocity varies only in the direction perpendicular to the flow, and the flow may be visualized as many sheets or laminae flowing parallel to the duct walls. Thus, this type of flow is referred to as laminar. In laminar flow, C_D depends on the square root of the pressure difference;

therefore, Q is proportional to Δp. At large Reynolds numbers, the flow becomes turbulent. The velocity at a given point fluctuates rapidly and at random, even if the net flow rate is constant. In turbulent flow, the discharge coefficient is constant at a fixed Reynolds number and therefore the flow Q is proportional to $\sqrt{\Delta p}$.

The case of fully developed flow impinging on a hole, nozzle, or orifice in a thin plate is also described by Equation (14). Again, for a sufficiently large value of the Reynolds number, the discharge coefficient is constant. The value of C_D for an orifice depends on Reynolds number and the relative areas of the orifice and the duct in which the orifice is placed.

This discussion of laminar and turbulent flow applies to constant area ducts with fully developed flow and orifices in such ducts. The openings in a building envelope are much less uniform in geometry. Generally, the flow never becomes fully developed, thereby preventing the applicability of the simple relations between Q and Δp. Each opening in the building envelope can still be described by Equation (14), where A is an equivalent cross-sectional area, and C_D depends on opening geometry and the pressure difference across it. Equation (15), commonly called the power law equation, is sometimes used instead:

$$Q = c(\Delta p)^n \tag{15}$$

where

c = flow coefficient, cfm/(in. of water)^n
n = flow exponent, dimensionless

Equation (15) only approximates the relationship between Q and Δp. In fact, the values of c and n depend on the range of Δp over which Equation (15) is applied and do not have a physical interpretation. Honma (1975) measured Q as a function of Δp for several simple openings, and the measured data were fit to Equation (15). The cracks with larger flow resistances, *i.e.*, greater flow lengths or narrower widths, tended to have an exponent n closer to 1 than did gaps with less resistance. For openings in the shell of a building, the value of n depends on the opening geometry, as well as on entrance and exit effects. Additional investigation of pressure/flow data on simple cracks by Chastain *et al.* (1987) further indicated the importance of adequately characterizing the three-dimensional geometry of openings and the entrance and exit effects. A modeling procedure was developed to determine the discharge coefficient in Equation (14) for the complex openings found in the building shell.

The combination of all the openings in a building's envelope produces a relationship between pressure difference and airflow rate for the whole building and is referred to as the air leakage of the building.

The air leakage of a building can be measured (as described in the section on air leakage) and is a physical property of the building envelope that depends on the envelope design, construction, and deterioration over time. A building's air leakage is measured by imposing a uniform pressure difference over the entire building envelope and measuring the airflow rate required to maintain this difference. Such a distribution of envelope pressures never occurs naturally, but it does provide a useful measure of the airtightness of a building.

NATURAL VENTILATION FLOW RATES

Natural ventilation is the intentional flow of outdoor air because of wind and thermal pressures through controllable openings. It can effectively control both temperature and contaminants, particularly in mild climates. Temperature control by natural ventilation is often the only means of providing cooling when mechanical air conditioning is not available. The arrangement, location, and control of ventilation openings should combine the driving forces of wind and temperature to achieve a desired ventilation rate and good distribution of ventilation air through the building.

Natural Ventilation Openings

Natural ventilation openings include: (1) windows, doors, monitor openings, and skylights; (2) roof ventilators; (3) stacks connecting to registers; and (4) specially designed inlet or outlet openings.

Windows transmit light and provide ventilation when open. They may open by sliding vertically or horizontally; by tilting on horizontal pivots at or near the center; or by swinging on pivots at the top, bottom, or side. The type of pivoting used is important for weather protection and airflow rate.

Roof ventilators provide a weatherproof air outlet. Capacity is determined by the ventilator's location on the roof; the resistance the ventilator and its duct work offer to airflow; its ability to use kinetic wind energy to induce flow by centrifugal or ejector action; and the height of the draft.

Natural draft or gravity roof ventilators can be stationary, pivoting, oscillating, or rotating. Selection criteria include ruggedness, corrosion resistance, stormproofing features, dampers and operating mechanisms, noise, cost, and maintenance. Natural ventilators can be supplemented with power-driven supply fans; the motors need only be energized when the natural exhaust capacity is too low. Gravity ventilators can have manual dampers or dampers controlled by thermostat or wind velocity.

A roof ventilator should be positioned so that it receives the full, unrestricted wind. Turbulence created by surrounding obstructions, including higher adjacent buildings, impairs a ventilator's ejector action. The ventilator inlet should be conical or bell mounted to give a high flow coefficient. The opening area at the inlet should be increased if screens, grilles, or other structural members cause flow resistance. Building air inlets at lower levels should be larger than the combined throat areas of all roof ventilators.

Stacks or vertical flues should be located where wind can act on them from any direction. Without wind, stack effect alone removes air from the room with the inlets.

Required Flow

The ventilation airflow rate required to remove a given amount of heat from a building can be calculated from Equation (16) if the quantity of heat to be removed and the indoor-outdoor temperature difference are known.

$$Q = H/c_p \rho (t_i - t_o) \tag{16}$$

where

Q = airflow rate required to remove heat, cfm
H = heat to be removed, Btu/min
c_p = specific heat of air, Btu/lb$_m$ · °F (about 0.24)
ρ = air density, lb$_m$/ft^3 (about 0.075)
$t_i - t_o$ = indoor-outdoor temperature difference, °F

Flow Caused by Wind

Factors that affect the ventilation rate due to wind forces include average speed, prevailing direction, seasonal and daily variation in speed and direction, and local obstructions such as nearby buildings, hills, trees, and shrubbery. Liddament (1988) reviews the relevance of wind pressure as a driving mechanism. A multiflow path simulation model was developed and used to illustrate the effects of wind on air change rate.

Wind speeds are usually lower in summer than in winter; directional frequency is also a function of season. There are relatively few places where speed falls below one-half the average for more than a few hours a month. Therefore, natural ventilation systems

are often designed for wind speeds of one-half the seasonal average. Equation (17) shows the quantity of air forced through ventilation inlet openings by wind or determines the proper size of openings to produce given airflow rates:

$$Q = C_4 C_v A V \tag{17}$$

where

Q = airflow rate, cfm
A = free area of inlet openings, ft^2
V = wind speed, mph
C_v = effectiveness of openings (C_v is assumed to be 0.5 to 0.6 for perpendicular winds and 0.25 to 0.35 for diagonal winds)
C_4 = unit conversion factor = 88.0

Inlets should face directly into the prevailing wind. If they are not advantageously placed, flow will be less than that in the equation; if unusually well placed, flow will be slightly more. Desirable outlet locations are (1) on the leeward side of the building directly opposite the inlet, (2) on the roof, in the low-pressure area caused by a flow discontinuity of the wind, (3) on the side adjacent to the windward face where low-pressure areas occur, (4) in a monitor on the leeward side, (5) in roof ventilators, or (6) by stacks. Chapter 14 gives a general description of the wind pressure distribution on a building. The inlets should be placed in the high-pressure regions; the outlets should be placed in the negative or low-pressure regions.

Flow Caused by Thermal Forces

If building internal resistance is not significant, the flow caused by stack effect can be expressed by:

$$Q = C_5 K A \left[2g\Delta h_{NPL} (T_i - T_o)/T_i\right]^{0.5} \tag{18}$$

where

Q = airflow rate, cfm
K = discharge coefficient for opening
Δh_{NPL} = height from midpoint of lower opening to NPL, ft
C_5 = unit conversion factor = 60
T_i = indoor temperature, °R
T_o = outdoor temperature, °R

Equation (18) applies when $T_i > T_o$. If $T_i < T_o$, replace T_i in the denominator with T_o, and replace $(T_i - T_o)$ in the numerator with $(T_o - T_i)$. An average temperature for T_i should be used if there is thermal stratification. If the building has more than one opening, the outlet and inlet areas are considered equal. The discharge coefficient K accounts for all viscous effects such as surface drag and interfacial mixing.

Estimation of Δh_{NPL} is difficult. If one window or door represents a large fraction (approximately 90%) of the total opening area in the envelope, the NPL is at the midheight of that aperture, and Δh_{NPL} equals to one-half its height. For this condition, flow through the opening is bidirectional, *i.e.*, air from the warmer side flows through the top of the opening, and air from the colder side flows through the bottom. Interfacial mixing occurs across the counterflow interface, and the orifice coefficient can be calculated (Kiel and Wilson 1986) according to:

$$K = 0.40 + 0.0025 \left|T_i - T_o\right| \tag{19}$$

If enough other openings are available, the airflow through the opening will be unidirectional and mixing cannot occur. A discharge coefficient of $K = 0.65$ should then be used. Additional information on stack-driven airflows for natural ventilation can be found in Foster and Down (1987).

Greatest flow per unit area of openings is obtained when inlet and outlet areas are equal; Equations (17) and (18) are based on this equality. Increasing the outlet area over inlet area, or vice versa, increases airflow but not in proportion to the added area. When openings are unequal, use the smaller area in the equations and add the increase, as determined from Figure 5.

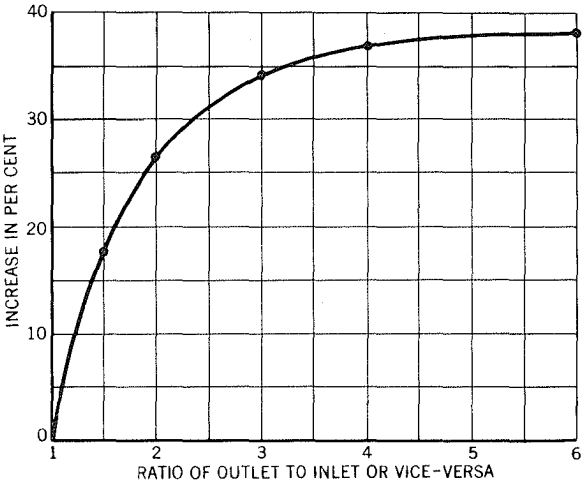

Fig. 5 Increase in Flow Caused by Excess of One Opening over Another

Natural Ventilation Guidelines

Several general guidelines should be observed in designing for natural ventilation. Some of these may conflict with other climate-responsive strategies (such as orientation and shading devices to minimize solar gain) or other design considerations.

1. In hot, humid climates, maximize air velocities in the occupied zones for bodily cooling. In hot, arid climates, maximize airflow throughout the building for structural cooling, particularly at night when the temperature is low.
2. Take advantage of topography, landscaping, and surrounding buildings to redirect airflow and give maximum exposure to breezes. Use vegetation to funnel breezes and avoid wind dams, which reduce the driving pressure differential around the building. Site objects should not obstruct inlet openings.
3. Shape the building to expose maximum surface area to breezes.
4. Use architectural elements such as wingwalls, parapets, and overhangs to promote airflow into the building interior.
5. The long facade of the building and the majority of the door and window openings should be oriented with respect to the prevailing summer breezes. If there is no prevailing direction, openings should be sufficient to provide ventilation regardless of wind direction.
6. Windows should be located in opposing pressure zones. Two openings on opposite sides of a space increase the ventilation flow. Openings on adjacent sides force air to change direction, providing ventilation to a greater area. The benefits of the window arrangement depend on the outlet location relative to the direction of the inlet airstream.
7. If a room has only one external wall, better airflow is achieved with two widely spaced windows.
8. If the openings are at the same level and near the ceiling, much of the flow may bypass the occupied level and be ineffective in diluting contaminants there.
9. The stack effect requires vertical distance between openings to take advantage of the stack effect; the greater the vertical distance, the greater the ventilation.
10. Openings in the vicinity of the NPL are least effective for thermally induced ventilation. If the building has only one

large opening, the NPL tends to move to that level, which reduces the pressure across the opening.

11. Greatest flow per unit area of total opening is obtained by inlet and outlet openings of nearly equal areas. An inlet window smaller than the outlet creates higher inlet velocities. An outlet smaller than the inlet creates lower but more uniform air speed through the room.
12. Openings with areas much larger than calculated are sometimes desirable when anticipating increased occupancy or very hot weather.
13. Horizontal windows are generally better than square or vertical windows. They produce more airflow over a wider range of wind directions and are most beneficial in locations where prevailing wind patterns shift.
14. Window openings should be accessible to and operable by occupants.
15. Inlet openings should not be obstructed by indoor partitions. Partitions can be placed to split and redirect airflow, but should not restrict flow between the building's inlets and outlets.
16. Vertical airshafts or open staircases can be used to increase and take advantage of stack effects. However, enclosed staircases intended for evacuation during a fire should not be used for ventilation.

INFILTRATION

Although the terms infiltration and air leakage are sometimes used synonymously, they are different, though related, quantities. Infiltration is the rate of uncontrolled air exchange through unintentional openings that occurs under given conditions, while air leakage is a measure of the airtightness of the building shell. The greater the air leakage of a building, the greater its infiltration rate, all else (weather, exposure, and building geometry) being equal. The infiltration rate is the air entering the structure and is equal to the exfiltration rate (air leaving the structure).

Infiltration may be reduced either by reducing the surface pressures driving the flow, or reducing the air leakage of the shell. Surface pressures caused by the wind can be reduced by changing the landscaping in the vicinity of the building (Mattingly and Peters 1977). Stack pressures can be reduced by increasing the airflow resistance between floors and from floors to any vertical shafts within the building, although this is almost exclusively an issue in tall buildings.

The infiltration rate of an individual building depends on weather conditions, equipment operation, and occupant activities. The rate can vary by a factor of five from weather effects alone (Malik 1978). When associating a building with an infiltration rate, it is important to provide the corresponding weather conditions and equipment status, or to describe it as a seasonal or annual average.

Typical infiltration values in housing in North America vary by a factor of about ten, from tight housing with seasonal average air change rates of about 0.2 per hour to housing with air exchange rates as great as 2.0 per hour. Figures 6 and 7 show histograms of infiltration rates measured in two different samples of North American housing (Grimsrud *et al.* 1982, Grot and Clark 1979). Figure 6 shows the average seasonal infiltration of 312 houses located in different areas in North America. The median infiltration value of this sample is 0.5 air changes per hour (ACH). Figure 7 represents measurements in 266 houses located in 16 cities in the United States. The median value of this sample is 0.90 ACH. The group of houses contained in the Figure 6 sample is biased toward new energy-efficient houses, while the group in Figure 7 represents older, low-income housing in the United States. Additional studies have found average values for houses in regional areas. Palmiter and Brown (1989) and Parker *et al.* (1990) found a a heating season average of 0.40 ACH (range: 0.13 to 1.11 ACH) for 134 houses in the Pacific Northwest. In a comparison of 292 houses incorporating energy-efficient features including measures to reduce air infiltration and provide ventilation heat recovery with 331 control houses, Parker *et al.* (1990) found an average of about 0.25 ACH (range: 0.02 to 1.63 ACH) for the energy-efficient houses versus a rate of 0.49 (range: 0.05 to 1.63 ACH) for the control. Ek *et al.* (1990) found an average of 0.5 ACH (range: 0.26 to 1.09) for 93 double-wide manufactured homes also in the Pacific Northwest. Canadian housing stock has been characterized by Yuill and Comeau (1989) and Riley (1990). While these do not represent random samples of North American housing, they indicate the distribution of infiltration rates expected in a group of buildings.

Occupancy influences have not been measured directly and vary widely. Desrochers and Scott (1985) estimate they add an average of 0.10 to 0.15 ACH to unoccupied values. Kvisgaard and Collet (1990) found that in 16 Danish dwellings, the users on average provided 63% of the total air change.

Grot and Persily (1986) found that eight recently constructed office buildings had infiltration rates ranging from 0.1 to 0.6 air changes per hour with no outdoor air intake. The infiltration rates of these buildings exhibited varying degrees of weather dependence, generally much lower than that measured in houses.

AIR EXCHANGE MEASUREMENT

The only reliable way to determine the air exchange rate of a building is to measure it. Several tracer gas measurement pro-

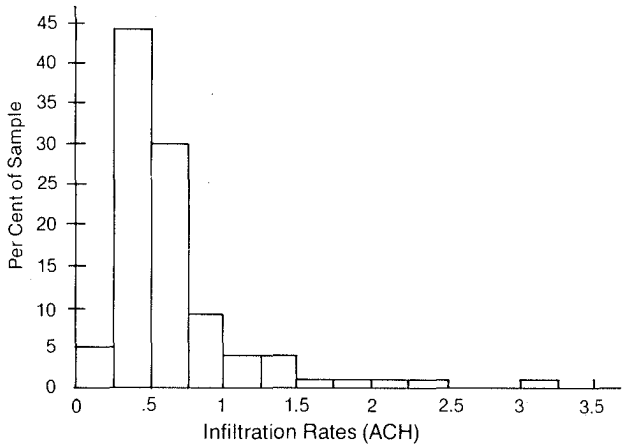

Fig. 6 Histogram of Infiltration Values—New Construction

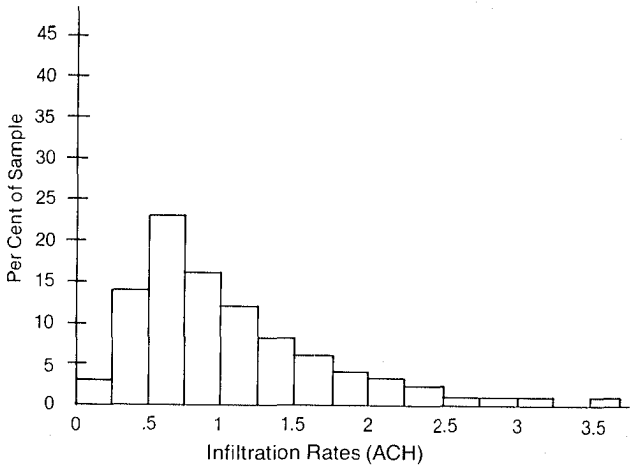

Fig. 7 Histogram of Infiltration Values—Low-Income Housing

cedures exist, all involving an inert or nonreactive gas used to label the indoor air (Hunt 1980, Sherman *et al.* 1980, Harrje *et al.* 1981, Lagus and Persily 1985, Dietz *et al.* 1986, Charlesworth 1988, Persily 1988, Fisk *et al.* 1989, Lagus 1989, Sherman 1989a, 1989b, Fortmann *et al.* 1990, Harrje *et al.* 1990, Persily and Axley 1990, Sherman 1990). The tracer is released into the building in a specified manner, and the concentration of the tracer within the building is monitored and related to the building's air exchange rate. A variety of tracer gases, and associated concentration detection devices, have been used. Desirable qualities of a tracer gas are detectability, nonreactivity, nontoxicity, and relatively low concentration in ambient air (Hunt 1980).

All tracer gas measurement techniques are based on a mass balance of the tracer gas within the building. Assuming the outdoor concentration is zero, this mass balance takes the form:

$$V(dc/d\theta) = F(\theta) - Q(\theta)c(\theta) \tag{20}$$

where

V = volume of space being tested, ft^3
$c(\theta)$ = tracer gas concentration at time θ
$dc/d\theta$ = time rate of change of concentration, min^{-1}
$F(\theta)$ = tracer gas injection rate at time θ, cfm
$Q(\theta)$ = airflow rate out of building at time θ, cfm
θ = time, min

In Equation (20), density differences between indoor and outdoor air are generally ignored for moderate climates; therefore, Q also refers to the airflow rate into the building. While Q is often referred to as the infiltration rate, any measurement includes both mechanical and natural ventilation in addition to envelope infiltration. The ratio of the air exchange rate Q to the volume being tested V has units of volume/time (often converted to ACH) and is called the air change rate I.

Equation (20) is based on the assumptions that no unknown tracer gas sources exist and that the airflow out of the building is the dominant process removing the tracer gas from the space, *i.e.*, the tracer gas does not react chemically within the space and/or is not absorbed onto interior surfaces. It is also based on the assumption that the tracer gas concentration within the building can be represented by a single value, *i.e.*, the tracer gas concentration is uniformly mixed within the space. Three different tracer gas procedures are used to measure air exchange rates: (1) decay, (2) constant concentration, and (3) constant injection.

Decay

The simplest tracer gas measurement technique is the decay method, which is a standardized procedure (ASTM 1990). In the decay method, a small amount of tracer gas is injected into the space and is allowed to mix with the interior air. After the injection, $F = 0$ and the solution to Equation (20) is:

$$c(\theta) = c_o e^{-I\theta} \tag{21}$$

where c_o is the concentration at $\theta = 0$.

Equation (21) is generally used to solve for I by measuring the tracer gas concentration periodically during the decay and fitting the data to the log form of Equation (21):

$$\ln c(\theta) = \ln c_o - I\theta \tag{22}$$

As with all tracer gas techniques, the tracer gas decay method has advantages and disadvantages. The advantages include the fact that Equation (21) is an exact solution to the tracer gas mass balance equation. Also, because logarithms of concentration are taken, only relative concentrations are needed, which can simplify the calibration of the concentration-measuring equipment. Finally, the tracer gas injection rate need not be measured, although it must be controlled so that the tracer gas concentrations are within the range of the concentration-measuring device. The concentration-measuring equipment can be located on site, or building samples can be collected in suitable containers and analyzed elsewhere.

The most serious problem with the decay technique is imperfect mixing of the tracer gas with the interior air, both at initial injection and during the decay. Equations (20) and (21) employ the assumption that the tracer gas concentration within the building is uniform. If the tracer is not well mixed, this assumption is not appropriate and the determination of I will be subject to errors. It is difficult to estimate the magnitude of the errors due to poor mixing, and little analysis of this problem has been done.

Constant Concentration

In the constant concentration technique, the tracer gas injection rate is adjusted to maintain a constant concentration within the building. If the concentration is truly constant, then Equation (20) reduces to:

$$Q(\theta) = F(\theta)/c \tag{23}$$

There is less experience with this technique than with the decay procedure, but several applications exist (Kumar *et al.* 1979, Collet 1981, Bohac *et al.* 1985, Fortmann 1990).

Because the tracer gas injection is continuous, it requires no initial mixing period. Another advantage is that the tracer concentration in each zone of the building can be separately controlled by injecting into each zone; thus, the amount of outdoor air flowing into each zone can be determined. This procedure has the disadvantage of requiring the measurement of absolute tracer concentrations and injection rates. Also, imperfect mixing of the tracer and the interior air causes a delay in the response of the concentration to changes in the injection rate. This delay in concentration response makes it impossible to keep the concentration constant, and therefore Equation (23) is only an approximation. The magnitude of these errors has not been well examined.

Constant Injection

In the constant injection procedure, the tracer is injected at a constant rate and the solution to Equation (20) becomes:

$$c(\theta) = (F/Q)(1 - e^{-I\theta}) \tag{24}$$

After sufficient time, the transient term reduces to zero, the concentration attains equilibrium, and Equation (24) reduces to:

$$Q = F/c \tag{25}$$

This relation is valid only when the air exchange rate is constant; thus, this technique is appropriate for systems at or near equilibrium. It is particularly useful in spaces with mechanical ventilation or with high air exchange rates. Constant injection requires the measurement of absolute concentrations and injection rates.

Dietz *et al.* (1986) introduced a special case of the constant injection technique. This technique uses permeation tubes as a tracer gas source. The tubes release the tracer at an ideally constant rate into the building being tested. A sampling tube packed with an adsorbent collects the tracer from the interior air at a constant rate by diffusion. After a sampling period of one week or more, the sampler is removed and analyzed to determine the average tracer gas concentration within the building during the sampling period.

Solving Equation (20) for c and taking the time average gives

$$< c > = < F/Q > = F < 1/Q > \quad (26)$$

where $< \ldots >$ denotes time average. (Note that the time average of $dc/d\theta$ is assumed to equal zero.)

Equation (26) shows that the average tracer concentration and the injection rate can be used to calculate the average of the inverse air exchange rate. The average of the inverse is less than the actual average, with the magnitude of this difference depending on the distribution of air exchange rates during the measurement period. Sherman and Wilson (1986) calculated these differences to be about 20% for one-month averaging periods. Differences greater than 30% have been measured when there were large changes in air exchange rate due to occupant airing of houses; errors from 5 to 30% were measured when the variation was due to weather effects (Bohac *et al.* 1987). Longer averaging periods and large changes in air exchange rates during the measurement periods generally lead to larger differences between the average inverse exchange rate and the actual average rate.

Multizone Air Exchange Measurement

Equation (20) is based on the assumption of a single, well-mixed enclosure, and the techniques described are for single-zone measurements. Airflow between internal zones and between the exterior and individual internal zones has lead to the development of multizone measurement techniques (Harrje *et al.* 1985, Sherman and Dickerhoff 1989, Fortmann *et al.* 1990, Harrje *et al.* 1990). This is important when considering the transport of pollutants from one room of a building to another. For a theoretical development, see Sinden (1978b). Multizone measurements will typically use multiple tracer gases for the different zones or the constant concentration technique. A proper error analysis is essential in all multizone flow determination (Charlesworth 1988, D'Ottavio *et al.* 1988).

AIR LEAKAGE

The air leakage of a building characterizes the relationship between the pressure difference across the building envelope and the airflow rate through the envelope (see Airflow through Openings). Building air leakage is a physical property of a building and is determined by its design, construction, seasonal effects, and deterioration over time. Although airtightness is just one factor in determining the air exchange rate of a building, it is useful for comparing buildings to one another or to airtightness standards, for evaluating design and construction quality, and for studying the effectiveness of airtightening retrofits. No simple relationship exists between a building's air leakage and its air exchange rate, but calculation methods do exist (see Calculating Air Exchange).

Measurement

While tracer gas measurement procedures provide building air exchange rates, they are somewhat expensive and time-consuming. In many cases, it is sufficient, or preferable, to measure the air leakage of a building with pressurization testing (Stricker 1975, Tamura 1975, Kronvall 1978, Blomsterberg and Harrje 1979, Gadsby and Harrje 1985). Fan pressurization is relatively quick and inexpensive and characterizes building envelope airtightness independent of weather conditions. In this procedure, a large fan or blower is mounted in a door or window and induces a large and roughly uniform pressure difference across the building shell (CGSB 1986, ASTM 1987). The airflow required to maintain this pressure difference is then measured. The leakier the building, the more airflow is necessary to induce a specific indoor-outdoor pressure difference. The airflow rate is generally measured at a series of pressure differences ranging from about 0.04 to 0.30 in. of water.

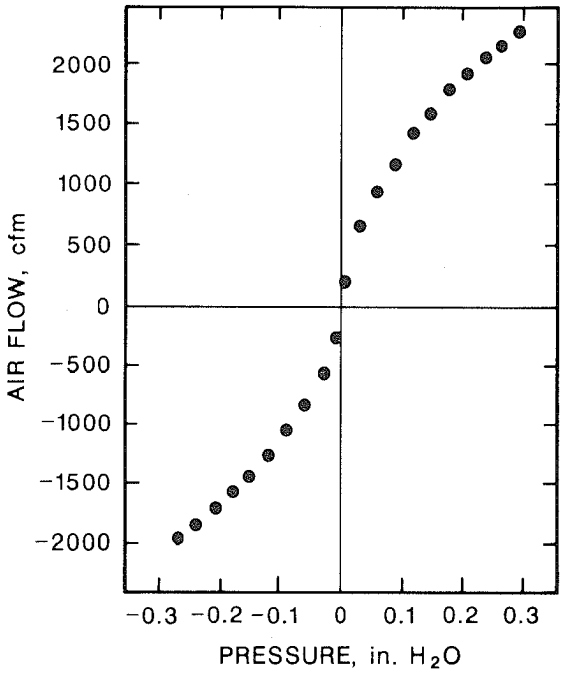

Fig. 8 Airflow Rate versus Pressure Difference Data from Whole House Pressurization Test

The results of a pressurization test, therefore, consist of several combinations of pressure difference and airflow rate data. An example of typical data is shown in Figure 8. These data points characterize the air leakage of a building and are generally converted to a single value that serves as a measure of the building's airtightness. There are several different measures of airtightness, most of which involve fitting the data to a curve in the form of Equation (15), *i.e.*, $Q = c\Delta p^n$. The airtightness ratings are based on airflow rates predicted at particular reference pressures by Equation (15). The basic difference between the different airtightness ratings is the value of the reference pressure.

In some cases, the predicted airflow rate is converted to an equivalent or effective leakage area by rearranging Equation (14) into the following form:

$$L = C_6 Q_r (\rho/2\Delta p_r)^{0.5}/C_D \quad (27)$$

where

L = equivalent or effective leakage area, in^2
Δp_r = reference pressure difference, in. of water
Q_r = predicted airflow rate at Δp_r (from curve fit to pressurization test data), cfm
C_D = discharge coefficient
C_6 = unit conversion factor = 0.186

All the openings in the building shell are combined into an overall opening area and discharge coefficient for the building when the equivalent or effective leakage area is calculated. Some users of the leakage area approach set the discharge coefficient equal to 1. Others set $C_D \cong 0.6$, *i.e.*, the discharge coefficient for a sharp-edged orifice. The leakage area of a building is, therefore, the area of an orifice (with an assumed value of C_D) that would produce the same amount of leakage as the building envelope at the reference pressure.

Whether an airtightness rating based on leakage area or a predicted airflow rate is used, either quantity is generally normalized by some factor to account for building size. These normalization factors include floor area, exterior envelope area, and building volume.

With the wide variety of possible approaches to normalization and reference pressure, and the use of the leakage area concept, many different airtightness ratings are being used. Reference pressure differences include 0.016, 0.04, 0.10, 0.20, and 0.30 in. of water. Reference pressures of 0.016 and 0.04 in. of water are advocated because they are closer to the pressures that actually induce air exchange and, therefore, better model the flow characteristics of the openings. While this may be true, they are outside the range of measured values in the test; therefore, the predicted airflow rates at 0.016 or 0.04 in. of water are subject to significant uncertainty. The uncertainty in these predicted airflow rates and the implications for quantifying airtightness are discussed in Persily and Grot (1985b), Chastain (1987), and Modera and Wilson (1990). Round robin tests by Murphy *et al.* (1991) to determine the repeatability and reproducibility of fan pressurization devices found that subtle errors in fan calibration or operator technique are greatly exaggerated when extrapolating the pressure versus flow curve out to 0.016 in. of water with errors as much as ±40% mainly due to the fan calibration errors at low flow.

Some common airtightness ratings include the effective leakage area at 0.016 in. of water assuming $C_D = 1.0$ (Sherman and Grimsrud 1980), the equivalent leakage area at 0.04 in. of water assuming $C_D = 0.611$ (CGSB 1986), and the airflow rate at 0.20 in. of water, divided by the building volume to give units of air changes per hour (Blomsterberg and Harrje 1979).

Leakage areas at one reference pressure can be converted to leakage areas at some other reference pressure according to:

$$L_{r,2} = L_{r,1} (C_{D,1}/C_{D,2}) (\Delta p_{r,2}/\Delta p_{r,1})^{n-0.5} \quad (28)$$

where

$L_{r,1}$ = leakage area at reference pressure $\Delta p_{r,1}$, in^2
$L_{r,2}$ = leakage area at reference pressure $\Delta p_{r,2}$, in^2
$C_{D,1}$ = discharge coefficient used to calculate $L_{r,1}$
$C_{D,2}$ = discharge coefficient used to calculate $L_{r,2}$
n = flow exponent from Equation (15)

A leakage area at one reference pressure can be converted to an airflow rate at some other reference pressure according to:

$$Q_{r,2} = C_7 C_{D,1} L_{r,1} (2/\rho)^{0.5} (\Delta p_{r,1})^{0.5-n} (\Delta p_{r,2})^n \quad (29)$$

where

$Q_{r,2}$ = airflow rate at reference pressure $\Delta p_{r,2}$, cfm
$L_{r,1}$ = leakage area at reference pressure, in^2
$C_{D,1}$ = discharge coefficient used to calculate $L_{r,1}$
C_7 = conversion factor = 5.39

Finally, a leakage area may be converted to a flow coefficient in Equation (15) according to:

$$c = C_7 C_D L (2/\rho)^{0.5} (\Delta p_r)^{0.5-n} \quad (30)$$

where

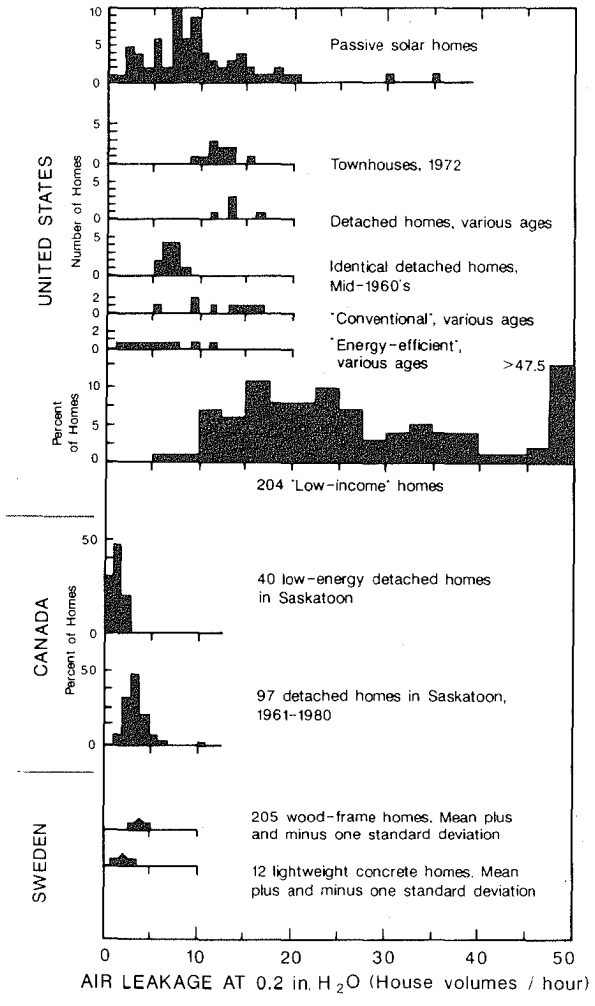
c = flow coefficient, cfm / (in. of water)^n
C_D = discharge coefficient used to calculate L
L = leakage area at reference pressure Δp_r
C_7 = conversion factor = 5.39

Equations (28) through (30) require the assumption of a value of n, unless it is reported with the measurement results. When fitting whole building pressurization test data to Equation (15), the value of n generally lies between 0.6 and 0.7. Therefore, using a value of n in this range is reasonable.

Fan pressurization measures a property of a building that ideally varies little with time and weather conditions. In reality, unless the wind and temperature difference during the measurement period are sufficiently mild, the pressure differences they induce during the test will interfere with the test pressures and cause measurement errors. Persily (1982) and Modera and Wilson (1990) have presented experimental studies of the effects of wind speed on pressurization test results. Several experimental studies have also shown variations on the order of 20 to 40% over a year in the measured airtightness in homes (Persily 1982, Kim and Shaw 1986, Warren and Webb 1986).

Several pressurization test results for residential buildings are presented in Figure 9 (Persily 1986). These results are in units of air changes per hour at 0.20 in. of water and show the wide range in airtightness among houses, even houses of identical design. The passive solar and energy-efficient data also show that houses that might be expected to be relatively airtight are not necessarily that tight. The houses in Sweden—which have a residential building airtightness standard of 0.3 air changes per hour at 0.20 in. of water for single-family detached houses (Swedish Building Code 1980)—are exceptionally tight, as are the houses in Canada.

ASHRAE *Standard* 119-1988 establishes air leakage performance levels for residential buildings. These levels are in terms of the normalized leakage L_n:



UNITED STATES
Number of Homes
Passive solar homes
Townhouses, 1972
Detached homes, various ages
Identical detached homes, Mid-1960's
"Conventional", various ages
"Energy-efficient", various ages
>47.5
Percent of Homes

12 lightweight concrete homes. Mean plus and minus one standard deviation
0 10 20 30 40 50
AIR LEAKAGE AT 0.2 in. H2O (House volumes / hour)

Fig. 9 Comparison of Pressurization Test Results

Table 2 Leakage Classes

Range of Normalized Leakage	Leakage Class
$L_n < 0.10$	A
$0.10 \leq L_n < 0.14$	B
$0.14 \leq L_n < 0.20$	C
$0.20 \leq L_n < 0.28$	D
$0.28 \leq L_n < 0.40$	E
$0.40 \leq L_n < 0.57$	F
$0.57 \leq L_n < 0.80$	G
$0.80 \leq L_n < 1.13$	H
$1.13 \leq L_n < 1.60$	I
$1.60 \leq L_n$	J

$$L_n = C_8 (L/A) (H/H_o)^{0.3} \quad (31)$$

where

L = effective leakage area at 0.016 in. of water (C_D = 1.0), in^2
A = gross floor area (within exterior walls), ft^2
H = building height, ft
H_o = reference height of one-story building = 8 ft
C_8 = conversion factor = 6940

Table 2 presents the leakage classes of *Standard* 119. The values of L_n in this table correspond approximately to annual average building air exchange rates in units of air changes per hour. The standard specifies appropriate leakage classes for a building based on climate.

Persily and Grot (1986) ran whole building pressurization tests in large office buildings, which showed pressurization airflow rate divided by the building volume is relatively low compared to that of houses. However, if these airflow rates are normalized by building envelope area instead of by volume, the results indicate envelope airtightness levels similar to those in typical American houses.

Air Leakage of Building Components

The fan pressurization procedure discussed earlier enables the measurement of whole building air leakage. The location and size of individual openings in building envelopes are extremely important, as they influence the air infiltration rate of a building as well as the heat and moisture transfer characteristics of the envelope. Additional test procedures exist for pressure testing individual building components such as windows, walls, and doors; they are discussed in ASTM *Standards* E 283 and E 783 for laboratory and field tests, respectively. The following sections discuss component air leakage in both residential and commercial buildings.

Leakage Distribution in Residential Buildings

Dickeroff *et al.* (1982) and Harrje and Born (1982) studied the air leakage of individual building components and systems. The following points summarize the percentages of whole building leakage area associated with various components and systems. The values in parentheses include the range determined for each component, and the mean of the range.

Walls (18 to 50%; 35%). Both interior and exterior walls contribute to the leakage of the structure. Leakage between the sill plate and the foundation, cracks below the bottom of the gypsum wall board, electrical outlets, plumbing penetrations, and leaks into the attic at the top plates of walls all occur. Since interior walls are not filled with insulation, open paths connecting these walls and the attic permit the walls to behave like heat exchanger fins within the conditioned living space of the house.

Ceiling details (3 to 30%; 18%). Leakage across the top ceiling of the heated space is particularly insidious because it reduces the effectiveness of insulation on the attic floor and contributes to infiltration heat loss. Ceiling leakage also reduces the effectiveness of ceiling insulation in buildings without attics. Recessed lighting, plumbing, and electrical penetrations leading to the attic are some particular areas of concern.

Heating system (3 to 28%; 18%). The location of the furnace or ductwork in conditioned or unconditioned spaces, the venting arrangement of a fuel-burning device, and the existence and location of a combustion air supply all affect leakage. Modera *et al.* (1991) and Robison and Lambert (1989), among others, have shown that the variability of leakage in ducts passing through unconditioned spaces is high, the coefficient of variation being on the order of 50%. Field studies have also shown that in-situ repairs can eliminate one-quarter to two-thirds of the observed leakage (Cummings and Tooley 1989, Cummings *et al.* 1990, Robison and Lambert 1989). The 18% contribution of ducts to total-leakage significantly underestimates their impact since during system operation, the pressure differentials across the duct leaks are approximately ten times higher than typical pressures across the envelope leaks (Modera 1989, Modera *et al.* 1991).

Windows and doors (6 to 22%; 15%). More variation is seen in window leakage among window types (*e.g.*, casement versus double-hung) than among new windows of the same type from different manufacturers (Weidt *et al.* 1979). Windows that seal by compressing the weatherstrip (casements, awnings) show significantly lower leakage than windows with sliding seals.

Fireplaces (0 to 30%; 12%). When a fireplace is not in use, poor-fitting dampers allow air to escape. Glass doors reduce excess air while a fire is burning but rarely seal the fireplace structure more tightly than a closed damper does. Chimney caps or fireplace plugs with telltale signs that warn they are in place effectively reduce leakage through a cold fireplace.

Vents in conditioned spaces (2 to 12%; 5%). Exhaust vents in conditioned spaces frequently have no dampers or dampers that do not close properly.

Diffusion through walls (< 1%). Diffusion, in comparison to infiltration through holes and other openings in the structure, is not an important flow mechanism. Typical values for the permeability of building materials at 0.02 in. of water produce an air exchange rate of less than 0.01 air changes per hour by wall diffusion in a typical house.

Component leakage areas. Table 3 shows effective leakage areas for a variety of residential building components at 0.016 in. of water with a C_D assumed equal to 1 (Colliver *et al.* 1992). The values in the table present results in terms of leakage area per component. Per unit component means either per component, per unit surface area, or per unit length of crack, whichever is appropriate. These leakage areas may be converted to leakage areas at other reference pressures, airflow rates, or flow coefficients using Equations (28) through (30).

Multifamily Building Leakage

Leakage distribution is particularly important in multifamily apartment buildings. These buildings often cannot be treated as single zones due to the internal resistance between apartments. Moreover, the leakage between apartments varies widely, tending to be small in modern construction, and ranging as high as 60% of the total apartment leakage in turn-of-the-century brick walk-up apartment buildings (Modera *et al.* 1985, Diamond *et al.* 1986). Little data on interzonal leakage has been reported because of the difficulty and expense of these measurements.

Commercial Building Envelope Leakage

The building envelopes of large commercial buildings are often thought to be quite airtight. The National Association of Architectural Metal Manufacturers specifies a maximum leakage per unit of exterior wall area of 0.060 cfm/ft^2 at a pressure difference of 0.30 in. of water exclusive of leakage through operable windows. Tamura and Shaw (1976a) found that air leakage measurements in eight Canadian office buildings with sealed windows, assum-

Note: Leakage areas are based on values found in the literature. The effective leakage area (in square inches) is based on a pressure difference of 0.016 in. of water and $C_d = 1$.

Abbreviations: ft^2 = gross area in square feet; ea = each; lftc = lineal feet of crack; lfts = lineal feet of sash

ing a flow exponent of 0.65 in Equation (15), ranged from 0.120 to 0.480 cfm/ft^2. Other measurements taken by Persily and Grot (1986) in eight U.S. office buildings ranged from 0.213 to 1.028 cfm/ft^2 at 0.30 in. of water. Therefore, office building envelopes are leakier than expected. Typical air leakage values per unit wall area at 0.30 in. of water are 0.10, 0.30, and 0.60 cfm/ft^2 for tight, average, and leaky walls, respectively (Tamura and Shaw 1976a).

Air Leakage through Internal Partitions

In large buildings, the air leakage associated with internal partitions becomes very important. Elevator, stair, and service shaft walls, floors, and other interior partitions are the major separations of concern in these buildings. Their leakage characteristics are needed to determine infiltration through exterior walls and airflow patterns within a building. These internal resistances are also important in the event of a fire to predict smoke movement patterns and evaluate smoke control systems.

Table 4 gives leakage areas (calculated at 0.30 in. of water with $C_D = 0.65$) for different internal partitions of commercial buildings (Klote and Fothergill 1983). Figure 10 presents examples of measured air leakage rates of elevator shaft walls (Tamura and Shaw 1976b), the type of data used to derive the values in Table 4. Chapter 47 of the 1991 ASHRAE *Handbook—Applications* should be consulted for models of performance of smoke control systems and their application.

Table 4 Leakage Areas for Internal Partitions in Commercial Buildings (at 0.3 in. of water and $C_D = 0.65$)

Leakage openings at the top of elevator shafts are equivalent to orifice areas of 620 to 1550 in^2. Air leakage rates through stair shaft and elevator doors are shown in Figure 11 as a function of average crack width around the door. The leakage areas associated with other openings within commercial buildings are also important for air movement calculations. These include interior doors and partitions, suspended ceilings in buildings where the space above the ceiling is used in the air distribution system, and other components of the air distribution system.

Air Leakage through Exterior Doors

Door infiltration depends on the type of door, room, and building. In residences and small buildings where doors are used infrequently, the air exchange associated with a door can be estimated based on air leakage through cracks between the door and the frame. A frequently opened single door, as in a small retail store, has a much larger amount of airflow. An ASHRAE research program provided data on air leakage characteristics of swinging door entrances (Min 1958, Tamura and Wilson 1966, 1967a) and revolving doors (Schutrum *et al.* 1961). A design chart (Min 1961) based on this report (Schutrum *et al.* 1961) evaluates infiltration through manual and power-operated revolving doors.

CONTROLLING AIR LEAKAGE

New Buildings

It is much easier to build a tight building than to tighten an existing building. Elmroth and Levin (1983), Eyre and Jennings (1983), Marbek (1984), and Nelson *et al.* (1985) provide information and construction details on airtight building design for houses. However, little corresponding information is available for commercial buildings.

A continuous air infiltration barrier is one of the most effective means of reducing air leakage through walls, around window and door frames, and at joints between major building elements. The air infiltration barrier can be installed on the inside of the wall framing, in which case it also usually functions as a vapor retarder, or on the outside of the wall framing, in which case it should have a permeance rating high enough to permit diffusion of water vapor from the wall. For a discussion of moisture transfer in building envelopes, see Chapters 20 and 21.

Fig. 11 Air-Leakage Rate of Door versus Average Crack Width

When the air infiltration barrier is also a continuous plastic film vapor retarder, particular care must be taken to ensure its continuity at all wall, floor, and ceiling joints; at window and door frames; and at all penetrations of the air-vapor barrier, such as electrical outlets and switches, plumbing connections, and utility service penetrations. Joints in the air-vapor barrier must be lapped and sealed. Plastic vapor retarders installed in the ceiling should be tightly sealed with the vapor retarder in the outside walls and continuous over the partition walls. A seal at the top of the partition walls prevents leakage into the attic; a plate on top of the studs generally gives a poor seal.

A continuous air-infiltration barrier installed on the outside of wall framing can eliminate many difficult construction details associated with the installation of continuous air-vapor barriers. Interior air-vapor barriers must be lapped and sealed at electrical outlets and switches, at joints between walls and floors and joints between walls and ceilings, and at plumbing connections penetrating the wall's interior finish. The exterior air-infiltration barrier can cover these problem areas with a continuous material. Joints in the air-infiltration barrier should be lapped and sealed or taped. Exterior air-infiltration barriers are generally made of a material stronger than plastic film and are more likely to withstand damage during construction. Sealing the wall against air leakage at the exterior of the insulation also cuts down on convective currents within the wall cavity, allowing insulation to retain more of its effectiveness.

Existing Buildings

The air-leakage sites must first be located to tighten the envelope of an existing building. As discussed earlier, air leakage in buildings is due not only to windows and doors, but to a wide range of unexpected and unobvious construction defects. Many important leakage sites can be very difficult to find. A variety of techniques developed to locate leakage sites are described in ASTM *Standard* E 1186 (1988) and Charlesworth (1988).

Once leakage sites are located, they can be repaired with materials and techniques appropriate to the size and location of the leak. Harrje *et al.* (1979), Diamond *et al.* (1982), and Energy Resource Center (1983) include information on airtightening in existing residential buildings. By using these procedures, the air leakage of residential buildings can be improved dramatically. Depending on the extent of the tightening effort and the experience of those doing the work, residential buildings can be tightened anywhere from 5 to more than 50% (Blomsterberg and Harrje 1979, Harrje and Mills 1980, Jacobson *et al.* 1986, Verschoor and Collins 1986, Giesbrecht and Proskiw 1986). Much less experience is available for airtightening large, commercial buildings, but the same general principles apply (Parekh *et al.* 1991, Persily 1991).

RESIDENTIAL VENTILATION SYSTEMS

Infiltration has traditionally met ventilation requirements for houses on the assumption that the building envelope is leaky enough. Possible difficulties with this approach include low ventilation when natural forces (temperature difference and wind) are weak, unnecessary energy consumption when such forces are strong, drafts in cold climates, lack of control of ventilation rates to meet changing needs, potential for interstitial condensation from exfiltration in cold climates, and no opportunity to recover the energy used to condition the ventilation air. The solution to these concerns is to have a reasonably tight building envelope and a properly designed and operated mechanical ventilation system.

ASHRAE *Standard* 119-1988, and the 1990 National Building Code of Canada encourage the transition to tighter envelope construction. Hamlin (1991) shows a 30% increase in airtightness of tract-built Canandian houses between 1982 and 1989. Also, 82% of the latter houses had natural air change rates below 0.3 ACH in March. Yuill *et al.* (1991) derived a procedure to show the extent to which infiltration contributes to ventilation rate requirements. As a result, the 1990 edition of the NBC of Canada has requirements for mechanical ventilation capability in all new dwelling units.

ASHRAE *Standard* 62-1989 gives ventilation rate requirements for houses, essentially 0.35 ACH with at least 15 cfm per occupant. The Canadian Standards Association *Standard* F 326 expands the requirements for residential mechanical ventilation systems to cover air distribution within the house, thermal comfort, minimum temperatures for equipment and duct work, system controls, pressurization and depressurization of the dwelling, installation requirements, and verification of compliance. Verification can be by design or by test, except that the total rate of outside air delivery must be measured.

Mechanical ventilation is being used in houses, especially in energy-efficient housing demonstration programs (Riley 1990, Palmiter *et al.* 1991). Possible systems can be characterized as local or central, exhaust or supply or balanced, with forced air or radiant/hydronic heating/cooling systems, with or without heat recovery, and with continuous operation or occupant controlled or demand controlled (*i.e.*, by pollutant sensing). Note that not all combinations are viable. Various options are described by Fisk *et al.* (1984), Hekmat *et al.* (1986), Sibbitt and Hamlin (1991), Palmiter *et al.* (1991), and Yuill *et al.* (1991).

The simplest systems use bathroom and kitchen fans to augment infiltration. Noise, installed capacity, life-time under continuous operation, distribution to all rooms (especially bedrooms), and energy-efficiency issues need to be addressed. Many present bath and kitchen fans are ineffective ventilators because of poor installations and designs. However, properly specified and installed exhaust fans can form part of good whole house ventilation systems and are so specified in some Canadian building codes.

Central supply systems use a furnace blower to induce airflow from outdoors and distribute it. However, if the blower is thermostatically controlled, it will operate intermittently and provide little ventilation in mild weather. If the blower operates continuously, cold drafts can be a problem when the furnance is off.

Central exhaust systems use leakage sites and, in some cases, intentional and controllable openings in the building envelope as the supply. Such systems are suitable for retrofit in existing houses. Energy can be recovered from the exhaust airstream with a heat pump to supplement domestic hot water and/or space heating.

For new houses with tightly constructed envelopes, balanced ventilation systems with passive heat recovery (air-to-air heat exchangers or heat recovery ventilators) are appropriate. Nearly equal rates of fan-induced supply and exhaust air flows over a heat exchanger, where heat and sometimes moisture is transferred between the airstreams. This reduces the energy consumption to condition the ventilation air by typically 60 to 80% (Cutter 1987). It also eliminates the thermal comfort problem that would occur if untempered air were introduced directly into the house. Airflow balance, leakage between streams, biological contamination of wet surfaces, and frosting are concerns associated with these devices.

Sibbitt and Hamlin (1991) found several low-cost mechanical systems that met CSA *Standard* F326 requirements, with proper design and commissioning. Palmiter *et al.* (1991) found that mechanical systems provide significant ventilation only when operated continuously. A separate ventilation system (air-to-air heat exchanger or exhaust air heat pump) or integrating an existing system with multispeed fans can best accomplish continuous ventilation. Continuous central supply systems are not recommended for cold climates, because they cause cold air drafts and condensation in the walls.

The type of ventilation system can be selected based on house leakage as defined in Table 2. Balanced air-to-air systems with heat recovery are optimal for tight houses (Leakage Classes A-C). The leakier the house, the larger will be the contribution from infiltration and the heat recovery ventilation will be less effective. In mild climates, these systems can also effectively be used in leakage classes D-F. Central exhaust systems should not be used for leakage classes A-C, unless special provisions are made for air inlets; otherwise, internal pressure will become too low during operation and backdrafting through fossil-fueled appliances could occur. Central exhaust systems are optimal for leakage classes D-F. Ventilation systems are normally not needed for leakage classes G-J, but for those cases in which it is, the central exhaust is usually the best choice.

CALCULATING AIR EXCHANGE

Techniques for calculating building air exchange rates have improved in recent years (Liddament 1983, Liddament and Allen 1983). This section describes several calculation procedures, ranging from simple estimation techniques to more physical models. The air exchange rate of a building cannot be reliably estimated a priori based on the building's construction or age or from a simple visual inspection. Some measurement is necessary, such as a pressurization test of envelope airtightness or a detailed quantification of the leakage sites and their magnitude. As discussed in the section on driving mechanisms, it is straightforward to calculate the air exchange rate of a building given the location and leakage function for every opening in the building envelope and between major building zones, the wind pressure coefficients over the building envelope, and any mechanical ventilation airflow rates. These inputs are generally unavailable for all except very simple structures or extremely well-studied buildings. Therefore, assumptions as to their values must be made. The appropriateness of these assumptions determines the accuracy of predictions of air exchange rates.

Empirical Models

These models of residential infiltration are based on statistical fits of infiltration rate data for specific houses. They use pressurization test results to account for house airtightness and take the form of simple relations between infiltration rate, an airtightness rating, and, in most cases, weather conditions. The models account for envelope infiltration only and do not deal with intentional ventilation. In one approach, the air changes per hour at 0.20 in. of water from a pressurization test is simply divided by a constant approximately equal to 20 (Sherman 1987). This technique does not account for the infiltration driving mechanisms on air exchange. Empirical models that do account for weather effects have been developed by Reeves *et al.* (1979), Kronvall (1980a), and Shaw (1981). The latter two models account for building air leakage using the values of c and n from Equation (15). The only other inputs required are the wind speed and temperature difference. Such empirical models predict long-term (one week) infiltration rates very well in the houses from which they were developed; they do not, however, work as well in other houses due to the building-specific nature of leakage distribution, wind pressure, and internal partitioning. Persily and Linteris (1983) and Persily (1986) show comparisons between measured and predicted house infiltration rates for these and other models. The average long-term differences between measurements and predictions are generally on the order of 40% for both models, although individual predictions can be off by 100% or more.

Single-Cell Models

Several procedures have been developed to calculate building air exchange rates that are based on physical models of the building interior as a single zone. These models are only appropriate to buildings with no internal resistance to airflow, and are therefore inappropriate to large, multizone buildings. Models of this type have been developed by the Institute of Gas Technology (IGT), Cole *et al.* (1980), the Building Research Establishment (Warren and Webb 1980), and the Lawrence Berkeley Laboratory (LBL) (Sherman and Grimsrud 1980). The LBL model has been widely used and serves as the basis of the calculation procedure described in the residential calculation example section that follows. It uses pressurization test results to characterize house air leakage through the effective leakage area at 0.016 in. of water ($C_D = 1$). In addition to the wind speed and temperature difference, the user must input information on distribution of leakage over the building envelope, a shielding parameter, and a local terrain coefficient. The predictive accuracy of this model can be very good (±7% for weekly, ±20% for short term) when the inputs are well known for the building in question (Sherman and Modera 1986), but the predictions are not as accurate when the inputs are not known. All these single-zone models are sensitive to the values of the inputs, and it is generally quite difficult to determine appropriate values. These models have exhibited average errors on the order of 40% for many measurements on groups of houses and can be off by 100% in individual cases (Persily 1986).

Multicell Models

Multicell models of air exchange treat buildings as a series of interconnected zones and assume that the air within each zone is well mixed. Several such models have been developed by Allard and Herrlin (1989), Etheridge and Alexander (1980), Liddament and Allen (1983), Walton (1984, 1989), Herrlin (1985), and Feustel and Raynor-Hoosen (1990). They are all based on a mass balance for each zone of the building. These mass balances are used to solve for an interior static pressure within the building by requiring that the inflows and outflows for each zone balance to zero. These models require the user to input a location and leakage function for every opening in the building envelope and relevant interior partitions, a value for the wind pressure coefficient C_p at the location of each building envelope leakage site, and any mechanical ventilation airflow rates. This detailed information is difficult to obtain for a building. Wind pressure coefficient data in the literature, air leakage measurement results from the building or its components, and air-leakage data from the literature, can be used. These models not only solve for whole building and individual zone air exchange rates, but also determine airflow rates between zones. These interzone airflow rates are useful for predicting pollutant transport within buildings and smoke movement patterns in the event of a fire. Multizone models have the advantage of providing a physically correct determination of airflow rates, and very complex representations of buildings can be easily modeled on personal computers; however, determining the correct inputs to these models is difficult.

Residential Calculation Example

This section presents a simple, single-zone approach to calculating air infiltration rates in houses based on the LBL model. The approach requires the effective leakage area at 0.016 in. of water, which can be obtained from a whole building pressurization test. If a test value is not available, the data in Table 3 can be used to estimate the leakage area of the building. To obtain the building's total leakage area, multiply the overall dimensions or number of occurrences of each building component by the appropriate table entry. The sum of the resulting products is the total building leakage area.

Table 5 gives the result of an example calculation of the effective leakage area of a residence. Each leakage component is identified in the first column and described in the second. The length, area, or number of components is in the third column. The fourth

column contains the leakage area per unit component, from Table 3, and the fifth contains the total leakage area associated with that component. The sum of the terms in the last column is the total leakage area of the building, in this case 131 in^2.

Using the effective leakage area, the airflow rate due to infiltration is calculated according to:

$$Q = L\,(A\Delta t + Bv^2)^{0.5} \tag{32}$$

where

Q = airflow rate, cfm
L = effective leakage area, in^2
A = stack coefficient, $cfm^2 \cdot in^{-4} \cdot °F^{-1}$
Δt = average indoor-outdoor temperature difference for time interval of calculation, °F
B = wind coefficient, $cfm^2 \cdot in^{-4} \cdot mph^{-2}$
v = average wind speed measured at local weather station for time interval of interest, mph

The infiltration rate of the building is obtained by dividing Q by the building volume. Table 6 presents values of A for one-, two-, and three-story houses. The value of the wind coefficient B depends on the local shielding class of the building and building height. Table 7 lists five different shielding classes. Table 8 presents values of B for one-, two-, and three-story houses in shielding classes one through five. In calculating the values in Tables 6 and 8, several assumptions are made regarding input to the LBL model. These include a terrain class of 3 (rural area with scattered obstacles), R = 0.5 (half of the building leakage in the walls), and $X = 0$ (equal amounts of leakage in the floor and ceiling). The height of the one-, two-, and three-story buildings are 8, 16, and 24 ft, respectively.

Example 1. Estimate the infiltration at design conditions for a two-story house in Lincoln, NB. The house has an effective leakage area of 77 in^2, a volume of 12,000 ft^3, and is surrounded by a thick hedge (Shielding Class 3).

Solution: The 97.5% design temperature for Lincoln is −2 °F. Assume a design wind speed of 15 mph. Choosing A (0.0313) from Table 6 and B (0.0086) from Table 8, the airflow rate due to infiltration is:

$$Q = 77\,[(0.0313 \times 70) + (0.0086 \times 15^2)]^{0.5}$$
$$= 156 \text{ cfm} = 9384 \text{ ft}^3/\text{h}$$

Table 5 Example of Calculation of Building Effective Leakage Area Based on Component Leakage Areas

Component	Description	D_i	L_i	D_iL_i
Sills	Uncaulked	142 ft	0.19 in^2/ft	27.0
Electrical outlets		20	0.08 in^2 ea	1.6
Windows	Sliding	141 ft^2	0.057 in^2/ft^2	11.4
Framing		141 ft^2	0.024 in^2/ft^2	
Exterior doors	Single	62 ft^2	0.11 in^2/ft^2	8.3
Framing		62 ft^2	0.024 in^2/ft^2	
Fireplace	Without damper	1	54.0 in^2 ea	54.0
Penetrations	Pipes	7	0.93 in^2 ea	6.5
Heating ducts	Ducts untaped, in basement	1	22.0 in^2 ea	22.0
			Calculated building leakage area L_c	=131 in^2

Table 6 Stack Coefficient A

	House Height (Stories)		
	One	Two	Three
Stack coefficient	0.0156	0.0313	0.0471

The infiltration rate I is equal to Q divided by the building volume:

$$I = (9384 \text{ ft}^3/\text{h}) / (12{,}000 \text{ ft}^3)$$
$$\text{or } I = 0.78 \text{ ACH}$$

Example 2. Calculate the average infiltration during a one-week period in January for a one-story house in Portland, OR. During this period, the average indoor-outdoor temperature difference is 30 °F, and the average wind speed is 6 mph.

The house has a volume of 9000 ft^3, an effective leakage area of 107 in^2, and is located in an area with buildings and trees within 30 ft in most directions (Shielding Class 4).

Solution: The airflow rate due to infiltration is:

$$Q = 107\,[(0.0156 \times 30) + (0.0039 \times 6^2)]^{0.5}$$
$$= 83.5 \text{ cfm} = 5000 \text{ ft}^3/\text{h}$$

The infiltration rate is, therefore:

$$I = (5000 \text{ ft}^3/\text{h}) / (9000 \text{ ft}^3)$$
$$I = 0.56 \text{ ACH}$$

This value of infiltration is an estimate of the average value over the one-week interval for which the weather information was obtained and averaged.

Example 3. Estimate the average infiltration over the heating season in a two-story house with a volume of 11,000 ft^3 and the leakage area calculated in Table 5 (131 in^2). The house is located on a lot with several large trees but no other close buildings (Shielding Class 3). The average wind speed during the heating season is 7 mph, while the average indoor-outdoor temperature difference is 36 °F.

Solution: From Equation (32), the airflow rate due to infiltration is:

$$Q = 131\,[(0.0313 \times 36) + (0.0086 \times 7^2)]^{0.5}$$
$$= 163 \text{ cfm} = 9780 \text{ ft}^3/\text{h}$$

The average infiltration is, therefore:

$$I = (9780 \text{ ft}^3/\text{h}) / 11{,}000 \text{ ft}^3$$
$$I = 0.89 \text{ ACH}$$

Again, this estimate is valid for the time interval used in computing the average values of the weather variables. Therefore, since the temperature difference and wind speed are values averaged over the entire heating season, the infiltration estimate is valid over the same interval.

Table 7 Local Shielding Classes

Class	Description
1	No obstructions or local shielding
2	Light local shielding; few obstructions, few trees, or small shed
3	Moderate local shielding; some obstructions within two house heights, thick hedge, solid fence, or one neighboring house
4	Heavy shielding; obstructions around most of perimeter, buildings or trees within 30 ft in most directions; typical suburban shielding
5	Very heavy shielding; large obstructions surrounding perimeter within two house heights; typical downtown shielding

Table 8 Wind Coefficient B

Shielding Class	House Height (Stories)		
	One	Two	Three
1	0.0119	0.0157	0.0184
2	0.0092	0.0121	0.0143
3	0.0065	0.0086	0.0101
4	0.0039	0.0051	0.0060
5	0.0012	0.0016	0.0018

BIBLIOGRAPHIC DATABASE

A database of bibliographic references which contains abstracts in English of technical papers covering air infiltration in buildings, AIRBASE, has been developed by the Air Infiltration and Ventilation Centre (AIVC 1992). Most of the articles are concerned with the prediction, measurement, and reduction of air infiltration and leakage rates. Selected abstracts are also included for papers relating to: indoor air quality, occupant behavior, thermal comfort, ventilation efficiency, natural and mechanical ventilation, wind pressure and its influence on infiltration, energy saving measures, and moisture and condensation.

CHAPTER 24

WEATHER DATA

Interior Design Conditions 24.1
Outdoor Design Conditions 24.1
Wind Data 24.2
Median of Annual Extremes 24.2
Interpolation between Stations 24.2
Weather-Oriented Design Factors 24.2
Weather Year for Energy Calculations (WYEC) 24.3
Other Weather Data 24.3
Climatic Conditions for the United States 24.4
Climatic Conditions for Canada 24.16
Climatic Conditions for Other Countries 24.18

THIS chapter presents weather station climatic conditions in the United States, Canada, and other countries. Design temperatures are based on the assumption that the frequency level of a specific temperature over a suitable time period will repeat in the future. The selected summer frequencies of 1%, 2.5%, and 5% and the winter frequencies of 99% and 97.5% enable the engineer to match the risk level desired for the problem at hand. At many locations, meteorological evidence indicates that the temperatures at the 1 and 99% levels may vary in the order of 2 to 4°F in any 15-year period from the previous 15-year period, and even more in any single year from the previous one. The proximity of the 99% level to the median of the annual extreme minimum temperatures indicates that extremely low temperatures occur in rare extended episodes rather than in long-term summations (Ecodyne Cooling Products 1980, Snelling 1985, Crow 1963).

Where stringent requirements for design conditions must be met, a consulting meteorologist with experience in applied climatology can evaluate special conditions, such as the formation of heat sinks in urban areas (heat islands) and the duration of extreme temperatures at project sites located remotely from reporting stations.

Annual degree-day tabulations for seven base temperatures in °F at 2546 stations in the United States can be found in *Climatography of the U.S.* (National Climatic Data Center 1992b). Annual degree-day tabulations for seven base temperatures in °C at 1195 stations in Canada are in *Canadian Climate Normals* (Atmospheric Environment Service 1981).

INTERIOR DESIGN CONDITIONS

ASHRAE *Standard* 55-1992 specifies thermal environmental conditions for the comfort of healthy people in buildings. For other conditions, refer to Chapter 8. Indoor design conditions for specific applications are suggested in Chapters 3 through 7 of the 1991 ASHRAE *Handbook—Applications*. Building codes may refer to the ASHRAE *Standard* 90 series or 100 series. Other legal restrictions on interior temperature set points and/or energy consumption may also apply.

OUTDOOR DESIGN CONDITIONS

The recommended design temperatures presented here are based on data from the National Climatic Data Center of NOAA, U.S. Air Force, U.S. Navy, Canadian Atmospheric Environment Service, and the weather organizations of the countries noted. Ecodyne Cooling Products (1980) gives other tabulations.

Temperatures at these stations, airports, and U.S. Air Force bases are measured each hour by trained observers and are recorded rounded off to the nearest whole degree, Fahrenheit. These recorded values have been statistically analyzed for a recent 5-year period of record and tabulated to the nearest whole degree, Fahrenheit, as shown in Tables 1, 2, and 3.

During the period 1965 through 1981, NOAA digitized only the three-hourly observations for most stations; therefore, the time frame for data in this tabulation is 1950 through 1964, when hourly data were available. The U.S. Air Force data used are for the period of 1957 through 1971. Although published records are for only 3-h intervals, hourly tapes are available. The frequency of occurrence of these recommended design temperatures has been machine tabulated from recorded hourly observations at the stations reporting hourly readings. Tabulated data are obtained from *Engineering Weather Data* (USAF 1978).

To make recommended design temperatures available for locations where hourly readings were not made, but where population concentrations, climatic variation, or geographical representation indicated a need, the data were adjusted by appropriate meteorological techniques from nearby stations reporting hourly data. Methods for interpolation are described in Ecodyne Cooling Products (1980) and Crow (1963).

Winter

Recommended design temperatures are presented in Column 5 of Tables 1, 2, and 3. Two frequency levels are offered for each station representing temperatures that have been equaled or exceeded by 99% or 97.5% of the total hours in the months of December, January, and February (a total of 2160 h) in the Northern Hemisphere and the months of June, July, and August in the Southern Hemisphere (a total of 2208 h). In a normal winter there would be approximately 22 h at or below the 99% value and 54 h at or below the 97.5% value. Column 9, the prevailing wind direction, is the wind direction occurring most frequently and the mean wind speed, which occurs coincidentally with the 97.5% dry-bulb winter design temperature. Column 10 is the median of the annual extreme minimum temperature. Snelling (1985) and Crow (1985) found that the duration in a single episode of extremely low temperatures below the 99% and 97.5% levels can continue for 3 to 5 days.

For Canadian stations, the two design values are based on only the month of January, because the temperature distribution in January in Canada is characteristic of an extremely cold month compared to the temperature distributions in December and February. The Canadian design temperatures are a few degrees lower than those based on three winter months (see Arctic Meteorology Research Group 1960, Boughner 1960).

Summer

Recommended design dry-bulb and wet-bulb temperatures and mean daily range are presented in Columns 6, 7, and 8 of Tables 1, 2, and 3. Column 6 provides dry-bulb temperatures with their corresponding coincident wet-bulb temperatures. In Table 3, the coincident wet-bulb temperatures are not available. The dry-bulb

The preparation of this chapter is assigned to TC 4.2, Weather Information.

temperatures represent values that have been equaled or exceeded by 1%, 2.5%, and 5% of the total hours during the months of June through September (a total of 2928 h) in the Northern Hemisphere and the months of December through March in the Southern Hemisphere (a total of 2904 h). The coincident wet-bulb temperature listed with each design dry-bulb temperature is the mean of all wet-bulb temperatures occurring at the specific dry-bulb temperature.

The mean daily range shown in Column 7 of Tables 1 and 2 is the difference between the average daily maximum and average daily minimum temperatures in the warmest month. In Table 3, the daily range is the long-term average. In Tables 1, 2, and 3, wet-bulb temperatures in Column 8 represent values that have been equaled or exceeded by 1%, 2.5%, and 5% of the hours during the summer months. These wet-bulb values were computed independently of the dry-bulb values and are not coincident with the design dry-bulb values in Column 6. Their coincident dry-bulb values have not been tabulated. Ecodyne Cooling Products (1980) has examples of the coincident dry-bulb with the extreme wet-bulb temperature.

In Column 9, the prevailing wind direction is the wind direction occurring most frequently coincident with the 2.5% dry-bulb summer design temperature. Column 10 gives the median of the annual extreme maximum and minimum temperature. In a normal summer, approximately 30 h would be at or above the 1% design value, and 150 h at or above the 5% design value. Snelling (1985) and Crow (1985) found that episodes of temperatures above the 1%, 2.5%, and 5% levels do not continue for more than 24 h.

For Canadian stations, the 1%, 2.5%, and 5% values are based on the month of July only, because the temperature distribution in July in Canada is characteristic of an extremely warm month compared with the temperature distributions of the adjacent months. The Canadian summer design values are a few degrees higher than those based on four summer months (see Arctic Meteorology Research Group 1960, Boughner 1960).

Design temperatures for individual months or other periods are not tabulated here but can be roughly approximated from bin data in USAF (1978). The Atmospheric Environment Service (1883-1987) has detailed monthly temperature percentiles and other data for 1345 Canadian locations. Data summaries for stations throughout the world are also available in Engineering Weather Data (USAF 1978) and Tables of Temperature, Relative Humidity and Precipitation for the World, Parts I-IV (Meteorological Office 1958).

WIND DATA

Winter

The prevailing wind direction is the wind direction occurring most frequently with the 97.5% dry-bulb winter design temperature. The mean wind speed (knots) is the average of those wind speed values occurring coincidentally with the 97.5% dry-bulb winter design temperature (USAF 1978).

At many stations, particularly in and near mountainous terrain, the prevailing wind direction for winter hours at the 97.5% level is strongly influenced by local terrain features. The wind speeds during this local down-valley drainage flow is generally 7 knots or less.

Summer

The prevailing wind direction is the wind direction occurring most frequently with the 2.5% dry-bulb summer design temperature (USAF 1978).

MEDIAN OF ANNUAL EXTREMES

In winter, the median of the annual extreme applies to the minimum temperatures. In summer, the median of the annual extreme applies to the maximum temperatures.

INTERPOLATION BETWEEN STATIONS

Data from many specific weather stations can supply a database for interpolation of expected conditions at nearby locations that lack data. Refer to Crow (1963) for examples of interpolation criteria. The stations included in Tables 1 and 2 were primarily selected because of their status as first-order weather stations having available hourly weather data. Additional locations were selected on the basis of population, climatic variations, or geographical representation. The design temperatures for stations lacking hourly data have been estimated from nearby stations with an hourly database.

The design data in Table 3 were compiled using techniques described by Ecodyne Cooling Products (1980). In *Engineering Weather Data* (USAF 1978), adjustments have been made for longer periods of record.

The statistics in these tables are presented as a guide only, and they should be used with caution for locations other than those measured. The design values at a building site may differ significantly from the reporting location. A meteorologist experienced in climatology can help interpret and extrapolate the data.

WEATHER-ORIENTED DESIGN FACTORS

The usual approach in air-conditioning system design involves computation of peak design load at a specific hour of a design day, using one of the frequency levels of design conditions in Tables 1, 2, or 3. While the values enumerated in this chapter are statistically accurate, certain precautions are recommended concerning their use. These figures are frequency distribution statistics for the ends of the distribution (see Ecodyne Cooling Products 1980, Snelling 1985, Crow 1963).

Design-day hourly profiles of dry-bulb temperatures with coincident wet-bulb temperatures have not been published. These profiles may be estimated by studying local climatology or by examining the daily range and peak design values.

Winter

Minimum temperatures usually occur between 6:00 A.M. and 8:00 A.M. suntime on clear days when the daily range is greatest. For residential applications or other applications where the occupancy is continuous throughout the day, the recommended design temperatures in Column 5 apply. With commercial applications or other applications where occupancy is only during hours near the middle of the day, design temperatures above the recommended minimum may apply. For example, in a supermarket or food store, lower temperatures during unoccupied times increase the shelf life of the merchandise and may reduce the heating plant size, but the recovery to acceptable occupancy levels must be considered in equipment selection and system design. Studies at several stations have found that the duration of extremely cold temperatures can continue below the 99% level for 3 days and below the 97.5% level for 5 days or more (see Ecodyne Cooling Products 1980, Snelling 1985, Crow 1963).

Summer

Maximum temperatures usually occur between 2:00 P.M. and 4:00 P.M. suntime with deviations on cloudy days when the daily range is less. When calculating building cooling loads, it is advisable to determine whether the structure is most sensitive to dry bulb, *i.e.*, extensive exterior exposure, or wet bulb, *i.e.*, outside ventilation. Then the appropriate design dry bulb with its coincident wet bulb from Column 6, or the appropriate design wet bulb from Column 8 with its coincident dry bulb (not shown) may be used. As noted previously, the design dry bulb (Column 6) and design wet bulb (Column 8) temperatures are not coincident. Comparing the coincident wet-bulb temperatures in Column 6 with the design wet-bulb temperatures in Column 8 and considering the daily range in

Column 7 illustrates this phenomenon. Using the design dry-bulb temperatures in Column 6 with the design wet-bulb temperatures in Column 8 will give computed loads significantly greater than actual loads.

Typically, the design dry-bulb temperatures should be used with the coincident wet-bulb temperatures in Column 6 in computing building cooling loads. The design wet-bulb temperatures in Column 8 are primarily intended for evaporative cooling processes, but may also be used for computing ventilation loads. Studies at several stations have found that the duration of extremely hot temperatures does not exceed one day (Ecodyne Cooling Products 1980, Snelling 1985, Crow 1963).

This chapter does not include design dew-point information. But the frequency of occurrence of the humidity ratio (which is obtained from the design dew-point temperature) and the coincident dry-bulb temperature is needed to size desiccant or indirect evaporative cooling systems, particularly those that control humidity.

Note that a dew point calculated from the design dry-bulb and mean coincident wet-bulb temperatures is generally significantly lower than the dew point that corresponds to the same nominal percentile. Thus, desiccant equipment will be significantly undersized if this method of calculating dew points is used for design. This is because the design dry bulb corresponds to extremes of sensible heat, not extremes of humidity ratio. Also, the design wet-bulb temperature cannot be used to estimate design dew points because the corresponding dry-bulb temperature is not included in these tables. Appropriate humidity information for design for various locations is often available from manufacturers of dehumidification and indirect evaporative cooling equipment.

For residential or other applications where the occupancy is continuous throughout the day, the recommended design temperature applies. For commercial applications or other applications where occupancy is only during hours near the middle of the day, design temperatures below the recommended maximum might apply. In some cases, the peak occupancy load occurs before the effect of the outdoor maximum temperature has reached the space by conduction through the building mass. In other cases, the peak occupancy loads may be in months other than the three or four summer months when the maximum outdoor temperature is expected; here design temperatures from other months will apply. Bin data distributions are available in *Engineering Weather Data* (USAF 1978) for three time periods during the day.

Energy consumption of the proposed system is a design concern often solved by intuition, experience, or simple calculation. Current energy programs include occupancy schedules, operating schedules, and weather data varying from hourly to seasonal. These programs may include off-peak design values. They may evaluate system control on days that are characterized as cloudy, small temperature change, windy warm A.M. and cool P.M., fair and warm, and fair and cool. A proposed system design should consider these weather conditions and their effect on temperature control before a final design is chosen and equipment selection is made.

WEATHER YEAR FOR ENERGY CALCULATIONS (WYEC)

Public domain and proprietary energy programs frequently require 8760 h of weather data. Several ASHRAE research projects have quantified weather data for use in energy calculations. Crow (1985) reports a weather year for energy calculations (WYEC) tape at 51 locations with 8760 h of data for each station. The data are in the TRY format, with solar data from 16 solar reporting stations, National Climatic Data Center (1981, 1991), and MacLaren *et al.* (1980). The year is made up of monthly data from the U.S. Weather Service 1440 series tapes selected closest to the long-term mean. Both temperature and solar radiation were examined for correlation and for closeness to the long-term mean. Adjustments were made to secure close compliance to the long-term mean by replacing days in the closest month with days from the same month in other years. At the connections (midnight), the temperatures were adjusted for fit. Erroneous data and atypical conditions were replaced with better data. This tape with accompanying text is available from ASHRAE headquarters.

Degelman (1985) derived bin data from the WYEC tapes for 51 locations in six time periods during the day.

OTHER WEATHER DATA

Sources. Typical Meteorological Year (TMY) tapes were prepared from U.S. Weather Services hourly surface data files for the period 1954 through 1972. A year of 8760 h for each of 249 stations was prepared based on the SOLMET database (National Climatic Data Center 1981). Nine indices (total horizontal radiation, maximum, minimum, and mean of dry bulb and dew point, and the maximum and mean of wind speed) were identified as critical. They were weighted with the solar index as 50%, and the rest at 50%. Typical months were identified by their closeness to long-term cumulative distribution functions.

In the final selection, lengths of hot or cold periods with sunny or cloudy days were used. Discontinuities between months were machine smoothed. The TMY is made up of the typical months selected. Missing and atypical data were not replaced. These tapes are recommended for active solar design problems (Insolation Data Manual 1980). Sandia National Laboratories (1988) include information about the potential yearly variation of the solar resource in various U.S. locations.

The *Climatology of the U.S.: Annual Degree-Days to Selected Bases* from the National Climatic Data Center (1992b) includes United States data for heating and cooling degree-days to seven base temperatures in °F. Similar Canadian data in °C are available through the Canadian Climate Centre, Atmospheric Environment Service.

Investigations at both the U.S. Bureau of Standards and at Lawrence Berkeley Laboratories have evaluated the mean daily threshold value for calculating degree-day deficiencies. Most residential buildings fit energy consumption data best when the base of 57 °F is used. This proven base is the result of the combination of prudent use of insulation and the use of many heat-producing appliances (Nall and Arens 1979). Chapter 28 describes the energy estimating methods using these data.

ASHRAE (1986) contain bin data on magnetic disks for personal computers. The data is derived from WYEC tapes for 51 locations in six time periods during the day. This data does not necessarily represent long-term climatic conditions. The data is primarily for use in comparing simplified energy evaluations with hourly simulated loads, where WYEC tapes were used.

Solar Radiation Data. Approximately 30 stations report solar radiation in the United States. Due to inconsistencies in the calibration of station measuring devices prior to 1975, the data were rehabilitated by the National Climatic Center (National Climatic Data Center 1981). The Canadian Climate Centre has prepared a merged solar and meteorological computer database for 50 stations (MacLaren *et al.* 1980).

Evaporative Cooling Data. Crow (1972) reports on weather data for the design of evaporative cooling systems in the United States and Canada. Frequency of occurrence of median wet-bulb temperatures versus dry-bulb temperature data are available with design recommendations in Chapter 46 of the 1991 ASHRAE *Handbook—Applications.*

Underground Structures. Kusuda (1968) analyzed underground temperature data for a few stations in the contiguous United States. Kusuda (1971) also reported on earth temperatures beneath five different surfaces.

[a] AP, AFB, following the station name designates airport or military airbase temperature observations. Co designates office locations within an urban area that are affected by the surrounding area. Undersigned stations are semirural and may be compared to airport data.

[b] Winter design data are based on the 3-month period, December through February.

[c] Summer design data are based on the 4-month period, June through September.

[d] Mean wind speeds occurring coincidentally with the 99.5% dry-bulb winter design temperature.

[a] AP following the station name designates airport temperature observations. Co designates office locations within an urban area that are affected by the surrounding area. Undesignated stations are semirural and may be compared to airport data.

[b] Winter design data are based on the month of January only.

[c] Summer design data are based on the month of July only. See also Boughner (1960).

[d] Mean wind speeds occurring coincidentally with the 99.5% dry-bulb winter design temperature.

CHAPTER 25

RESIDENTIAL COOLING AND HEATING LOAD CALCULATIONS

Residential Features 25.1
COOLING LOAD 25.1
Cooling Load Components 25.1
Selecting Cooling Equipment 25.5
HEATING LOAD 25.6
General Procedure 25.6
Selecting Heating Design Conditions 25.7
Estimating Temperatures in Adjacent Unheated Spaces .. 25.8
Calculating Heat Loss from Crawl Spaces 25.9
Calculating Transmission Heat Loss 25.10
Calculating Infiltration Heat Loss 25.13
PICK-UP LOAD 25.14

The procedures described in Chapter 26 may be used to calculate a heating or cooling load for residential buildings. However, this chapter covers the engineering basis of modified residential load calculation procedures for the non-engineer.

RESIDENTIAL FEATURES

The unique features distinguishing residences from other types of buildings, with respect to heating and cooling load calculation and equipment sizing, are:

- Unlike many other structures, residences are usually occupied, and conditioned, for 24 h a day, virtually every day of the cooling and the heating season.
- Residential system loads are primarily imposed by heat loss or gain through structural components and by air leakage or ventilation. Internal loads, particularly those from occupants and lights, are small in comparison to those in commercial or industrial installations.
- Most residences are conditioned as a single zone. Unit capacity cannot be redistributed from one area to another as loads change from hour to hour; however, exceptions do occur.
- Most residential cooling systems use units of relatively small capacity (about 18,000 to 60,000 Btu/h cooling, 60,000 to 110,000 Btu/h heating). Since loads are largely affected by outside conditions and few days each season are design days, only a partial load exists during most of the season; thus, an oversized unit is detrimental to good system performance, especially for cooling in areas of high wet-bulb temperature.
- Dehumidification occurs only during cooling unit operation, and space condition control is usually restricted to use of room thermostats (sensible heat-actuated devices).
- Multifamily living units are similar to single-family, detached houses, but each living unit may not have surfaces exposed in all directions. This impacts load calculation.

Categories

Single-family detached. A house in this category usually has exposed walls in four directions, often more than one story, and a roof. The cooling system is a single-zone, unitary system with a single thermostat. Two-story houses may have separate cooling systems for each floor. The rooms are reasonably open and generally have a centralized air return. In this configuration, air and load from rooms is mixed, and a load-leveling effect, which requires a different distribution of air to each room than a pure commercial system, results. Since the amount of air supplied to each room is based on the load for that room, proper load calculation procedures must be used.

Multifamily buildings. Unlike single-family detached units, multifamily units do not have exposed surfaces facing in all directions. Rather, each unit has only one or two exposed surfaces and possibly a roof. Two exposed walls will be at right angles, and both east and west walls will not be exposed in a given living unit. Each living unit has a single unitary cooling system or a single fan coil unit, and the rooms are relatively open to one another. This configuration does not have the same load-leveling effect as a single-family detached house, and it is not a commercial building. Therefore, a specific load calculation procedure is required.

Other categories. Many buildings do not fall into either of the above categories. Critical to the designation of a single-family detached building is the presence of both east and west walls. Therefore, some multifamily structures should be treated as single-family detached when the exposed surfaces are oriented in a particular way. Examples include duplexes or apartments with exposed (1) east, west, and south, or (2) east, west, and north walls, with or without a roof; and apartments, town houses, or condominiums with only east and west or north and south exposed walls.

COOLING LOAD

COOLING LOAD COMPONENTS

A cooling load calculation determines total sensible cooling load due to heat gain (1) through structural components (walls, floors, and ceilings); (2) through windows; (3) caused by infiltration and ventilation; and (4) due to occupancy. The latent portion of the cooling load is evaluated separately. While the entire structure may be considered a single zone, equipment selection and system design should be based on a room-by-room calculation. To properly design the distribution system, the amount of conditioned air required by each room must be known.

Peak Load Computation

To select a properly sized cooling unit, the peak or maximum load (block load) for each zone must be computed. Since this procedure may vary considerably for different types of buildings, each building type has to be considered; the block load for a single-family detached house with one central system is the sum of all the room loads. If the house has a separate system for each zone, each zone block load (*i.e.*, the sum of the loads for all rooms in each zone) is required. When a house is zoned with one central cooling system, the block load must be computed for the complete house as if it were one zone. In multifamily structures, each living unit has a zone load that equals the sum of the room loads. For apartments with separate systems, the block load for each unit establishes the system size. Apartment buildings with a central

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

cooling system (*i.e.*, a hydronic system with fan coils in each apartment) require a block load calculation for the complete structure to size the central system; each unit load establishes the size of the fan coil and air distribution system for each apartment. One of the methods discussed in Chapter 26 may be used for the block load.

Indoor Temperature Swing

As demonstrated in the section Transfer Function Method in Chapter 26 for hour-by-hour load calculations, allowing for a swing in indoor temperature results in lower peak loads. Since the indoor temperature does swing, such an allowance gives a more reasonable equipment capacity. The tables in this section are based on an assumed indoor temperature swing of not more than 3 °F on a design day, when the residence is conditioned for 24 h per day and the thermostat is set at 75 °F.

Cooling Load Due to Heat Gain through Structure

The sensible cooling load due to heat gains through the walls, floors, and ceilings of each room is calculated using appropriate cooling load temperature differences and U-values for summer conditions (Tables 1 and 2). For ceilings under naturally vented attics or beneath vented flat roofs, use the combined U-value for the roof, vented space, and ceiling. The mass of the walls is a variable in Table 2 and is important in calculating energy use, but it is not used in Table 1 because of the averaging technique required to develop the CLTDs. Values in Tables 1 and 2 assume a dark color, since color is an unpredictable variable in any residence.

Daily range (outdoor temperature swing on a design day) significantly affects the equivalent temperature difference. Tables 1 and 2 list daily temperature ranges classified as high, medium, and low. Tables 1, 2, and 3 in Chapter 24 list outdoor daily ranges for different locations.

Cooling Load Due to Heat Gain through Windows

Direct application of procedures for calculating cooling load due to heat gain for flat glass (discussed in Chapters 26 and 27) results in unrealistically high cooling loads for residential installations. Window glass load factors (GLF) modified for single and multifamily residential cooling load calculations, and including solar heat load plus air-to-air conduction, are given in Tables 3 and 4. Table 5 lists the shading coefficients and U-value used to compile Tables 3 and 4.

[a]Cooling load temperature differences (CLTDs) for single-family detached houses, duplexes, or multifamily, with both east and west exposed walls or only north and south exposed walls, °F.
[b]L denotes low daily range, less than 16 °F; M denotes medium daily range, 16 to 25 °F; and H denotes high daily range, greater than 25 °F.

In application, the area of each window is multiplied by the appropriate GLF. The effects of permanent outside shading devices should be considered separately in determining the cooling load. Shaded glass is considered the same as north-facing glass. The shade line factor (SLF) is the ratio of the distance a shadow falls beneath the edge of an overhang to the width of the overhang (Table 6). Therefore, assuming the overhang is at the top of the window, the shade line equals the SLF times the overhang width. The shaded and sunlit glass areas may then be computed separately. The tabulated values are the average of the shade line values for 5 h of maximum solar intensity on each wall orientation shown. Northeast- and northwest-facing windows are not effectively protected by roof overhangs; in most cases, they should not be considered as shaded.

Infiltration

Natural air leakage in residential structures is less in summer than in winter, largely because wind velocities are lower in most localities. The data in Tables 7 and 8 showing space air changes per hour (ACH) apply to both single- and multifamily housing, although most of the raw data was for single-family structures (McQuiston 1984). Construction may be defined as follows:

Tight. Good multifamily construction with close-fitting doors, windows, and framing is considered tight. New houses with full

Shadow length below the overhang equals the shade line factor times the overhang width. Values are averages for the 5 h of greatest solar intensity on August 1.

vapor retardant, no fireplace, well-fitted windows, weatherstripped doors, one story, and less than 1500 ft^2 floor area fall into this category.

Medium. Medium structures include new, two-story frame houses or one-story houses more than 10 years old with average maintenance, a floor area greater than 1500 ft^2, average fit windows and doors, and a fireplace with damper and glass closure. Below-average multifamily construction falls in this category.

Loose. Loose structures are poorly constructed single- and multifamily residences, with poorly fitted windows and doors. Examples include houses more than 20 years old, of average maintenance, a fireplace without damper or glass closure, or more than an average number of vented appliances. Average mobile homes are in this category.

Ventilation

Residential air-conditioning systems may introduce outdoor air, although it is not a code requirement in most localities. Positive ventilation should be considered, however, if the anticipated infiltration just discussed is less than about 0.5 air changes per hour. When positive means of introducing outdoor air are used, controls, either manual or automatic, should be provided, and an energy recovery device should be considered.

Occupancy

Even though occupant density is low, occupancy loads should be estimated. Sensible heat gain per sedentary occupant is assumed to be 230 Btu/h. To prevent gross oversizing, the number of occupants should not be overestimated. Recent census studies recommend that the total number of occupants be based on two persons for the first bedroom, plus one person for each additional bedroom. The occupancy load should then be distributed equally among the living areas, because the maximum load occurs when most of the residents occupy these areas.

Household Appliances

Appliance loads are concentrated mainly in the kitchen and laundry areas. Based on contemporary living conditions in single-family houses, a sensible load of 1600 Btu/h should be divided between the kitchen and/or laundry and the adjoining room or

Table 7 Air Change Rates as Function of Airtightness

rooms. For multifamily units, the sensible heat gain values should be about 1200 Btu/h. These values assume that the cooking range and clothes drier are vented. Further allowances should be considered when unusual lighting intensities, computers, or other equipment are present.

Air Distribution System—Heat Loss/Gain

Whenever the air distribution system is outside the conditioned space, *i.e.*, in attics, crawl spaces, or other unconditioned spaces, heat loss or gains to the ducts or pipes must be included in the calculated load and should be considered in equipment selection.

Latent Heat Sources

The latent cooling load has three main sources: outdoor air, occupants, and miscellaneous sources, such as cooking, laundry, and bathing. These miscellaneous latent loads are largely covered by outdoor air, because most residences have exhaust fans and clothes driers that vent most of the moisture from these sources. This vent air is accounted for in the infiltration calculation. McQuiston (1984) estimated latent load factors for typical houses located in geographic regions, ranging from very dry to very wet, using the transfer function method (Figure 1). A latent factor (LF) (LF = 1/SHF) of 1.3 or a SHF (SHF = sensible load/total load) of 0.77 matches the performance of typical residential vapor compression cooling systems. Homes in almost all other regions of North America have cooling loads with a SHF greater than 0.77 and latent factors less than 1.3. Figure 1 may be used to estimate the total cooling load by reading LF as a function of the design humidity ratio and airtightness. Then $q_{total} = (LF)q_{sensible}$. If the humidity ratio is less than 0.01, set LF = 1.0.

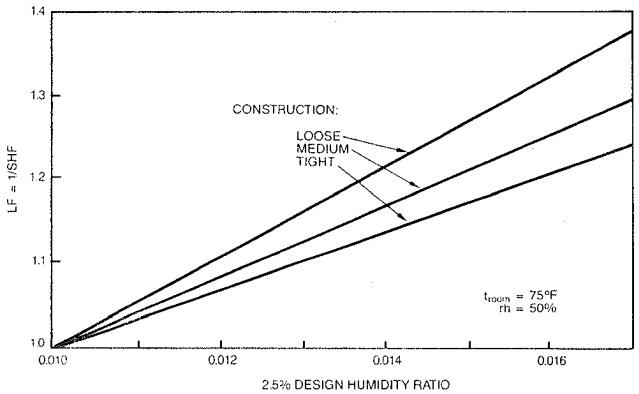

Fig. 1 Effect of Infiltration on Latent Load Factor

SELECTING COOLING EQUIPMENT

Residential cooling equipment that is flexible in application helps match the space SHF to the system. Usually, equipment is designed for a standard operating condition of 80 °F db and 67 °F wb air entering the coil, an airflow of 400 cfm per ton of refrigeration, and a SHF of 0.77 (LF = 1.3). Most regions require a coil SHF greater than 0.77; therefore, a mismatch is not unusual and can be acceptable. A coil designed with a given latent capacity generally transfers more sensible heat in the absence of moisture in the air, but not in the same amount as the design latent heat transfer capacity.

Cooling equipment should be sized on the basis of the estimated sensible cooling load, taking into account the effect of outdoor ambient conditions on the unit performance. The unit should not be oversized more than 25% of the estimated sensible load or the next available size. After selecting a unit, its latent capacity should be checked to ensure that it is equal to or greater than the calculated latent cooling load. The latent capacity of the unit will generally be ample except in very wet climates with excessive infiltration. If the latent cooling capacity is less than the calculated latent load, the unit size must be increased.

The cooling load calculation procedures are summarized in Table 9.

Example 1. A single-family detached house (Figure 2) is located in a southwestern state at 36 °N latitude.

Roof construction. Conventional roof-attic-ceiling combination, vented to remove moisture with 6 in. of fibrous batt insulation and vapor retardant (U = 0.05 Btu/h·ft^2·°F).

Wall construction. Frame with 4 in. face brick, 3.5 in. fibrous batt insulation, 0.75 in. polystyrene sheathing, and 0.5 in. gypsum plaster board (U = 0.06 Btu/h·ft^2·°F).

Floor construction. 4 in. concrete slab on grade.

Fenestration. Clear double glass, 0.125 in. thick, in and out. Assume closed, medium color venetian blinds. The window glass has a 2-ft overhang at the top.

Doors. Solid core flush with all-glass storm doors (U = 0.32 Btu/h·ft^2·°F).

Outdoor design conditions. Temperature of 96 °F dry bulb with a 24 °F daily range and a humidity ratio of 0.0136 lb vapor/lb dry air (74.6 °F wet bulb).

U-values for all external surfaces are based on a 7.5 mph wind velocity.

Indoor design conditions. Temperature of 75 °F dry bulb and 50% rh.

Occupancy. Four persons, based on two for the master bedroom and one for each additional bedroom. Assign to the living room.

Appliances and lights. Assume 1600 Btu/h for the kitchen, and assign 50% to the living room. Assume 1600 Btu/h for the utility room, and assign 25% to the kitchen and 25% to the storage room.

The conditioning equipment is located in the garage, and the construction of the house is considered average.

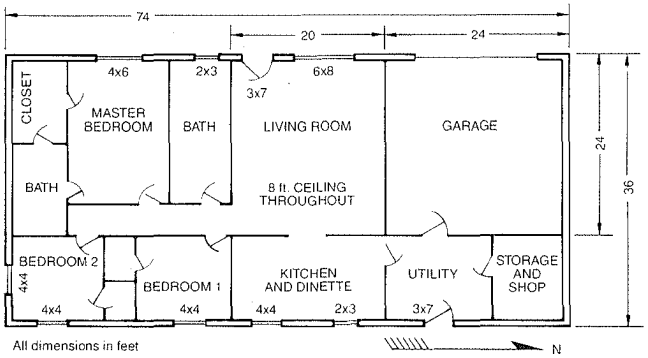

Fig. 2 Floor Plan of Single-Family Detached House

Table 9 Summary of Procedures for Residential Cooling Load Calculations

Load Source	Equation	Tables and Notes
Glass and window areas	$q = (GLF)A$	Glass load factors may be found in Tables 3 and 4 according to window orientation, type of glass, type of interior shading, and outdoor design temperature. The GLF includes effects of both transmission and solar radiation. Glass shaded by overhangs is treated as north glass. Table 6 gives shade line factors.
Doors	$q = U_w A$ (CLTD)	Door CLTD are in Tables 1 and 2 according to orientation, outdoor design temperature, and design daily temperature range.
Above-grade exterior walls	$q = U_w A$ (CLTD)	Wall CLTD values are in Tables 1 and 2 based on the outdoor design temperature, daily range, and orientation.
Partitions to unconditioned space	$q = U_p A \Delta t$	Where Δt is the temperature difference across the partition.
Ceilings and roofs	$q = U_r A$ (CLTD)	Tables 1 and 2 for CLTD, based on outdoor design temperature and daily range.
Exposed floors	$q = U_f A$ (CLTD)	Tables 1 and 2 for CLTD, according to outdoor design temperature and daily range.
Infiltration	$q = 1.1\,Q\Delta t$ Q = ACH (room volume)/60	Air change rates are given in Tables 7 and 8.
Internal loads— People, appliances, lights	Plan 230 Btu/h per person.	Divide occupants evenly among rooms not used as bedrooms. If number of occupants is not known, assume two people for first bedroom and one person for each additional bedroom. The appliance and light load of 1600 Btu/h is divided between the kitchen and adjoining room and the laundry and adjoining room. Use 1200 Btu/h for multifamily units.
Total loads	Total cooling load = LF (Sum of individual sensible cooling load components)	Load factors are from Figure 1 according to outdoor design humidity ratio and airtightness classification.

q = sensible cooling load, Btu/h
Δt = design temperature difference between outside and inside air, °F
A = area of applicable surface, ft^2
U = U-factors for appropriate construction, Btu/h·ft^2·°F
Q = volumetric airflow rate, ft^3/min
ACH = air changes per hour, 1/h
GLF = glass load factor, Btu/h·ft^2
CLTD = cooling load temperature difference, °F
LF = latent load multiplier

Find the sensible, latent, and total cooling load; size the cooling unit; and compute the air quantity for each room.

Solution: The cooling load must be made on a room-by-room basis to determine the proper distribution of air. The calculations follow the procedure just outlined.

Walls, roof, windows, and doors. The calculations for the living room and the kitchen, where $q = UA$ (CLTD) for the walls, roof, and door and $q = A$ (GLF) for the windows, are outlined in Table 10. The glass shaded by the overhang is treated as north-facing glass, with the shaded area computed using Table 6.

The internal and infiltration sensible cooling loads are computed as follows.

For the living room:

Infiltration. Using Table 8,

Q = ACH (room volume)/60

$Q = 0.5 \times 3840/60 = 32$

$q = 1.1\, Q(t_o - t_i) = 1.1\, Q\, \Delta t$

$q = 1.1 \times 32(96 - 75) = 740$ Btu/h

Occupants. Assuming 230 Btu/h per person,

$q = 230 \times$ (persons)

$q = 230 \times 4 = 920$ Btu/h

Appliances. Assuming that 50% of the kitchen appliance load is picked up in the living room,

$q = 0.5 \times$ (kitchen appliance load)

$q = 0.5 \times 1600 = 800$ Btu/h

For the kitchen:

Infiltration.

$Q = 0.5 \times 1920/60 = 16$

$q = 1.1 \times 16(96 - 75) = 370$ Btu/h

No occupants.

$q = 0$

Appliances. Assuming 25% of the utility appliance load is picked up in the kitchen,

$q = (1600/2) + (1600/4) = 1200$ Btu/h

Table 10 Transmission Cooling Load for Example 1

Duct loss (10%)						1910	
Outdoor ventilation air						1600	
					Total	22605	Btu/h

For the total sensible cooling load for these two rooms and the cooling load for the remaining rooms, see Table 11. At this point, the sensible cooling load for the house is about 19,100 Btu/h. Depending on the design of the air distribution system, heat losses from the supply and return ducts may add to the cooling load. These may be more accurately estimated after designing the system; however, to size the cooling unit, duct losses should be included initially. If all ducts are in the attic space, a duct loss of 10% of the space sensible cooling load is reasonable. For a counterflow system, with ducts below the slab, a 5% loss is more reasonable.

An infiltration rate of 0.5 ACH may not be adequate for good indoor air quality, so some outdoor air should be introduced. This additional cooling load may be estimated in the same way as the infiltration load.

Assume that the entire duct system is in the attic, *i.e.*, the total sensible cooling load with a 10% duct loss is 1.1 × 19,095 or 21,000 Btu/h. Also, assume that additional outdoor air is needed to assure good indoor air quality, so the total infiltration and outdoor ventilation air is 0.75 ACH. This increases the infiltration rate by 50% or about 1600 Btu/h. The total sensible cooling load is then increased to 22,605 Btu/h (Table 11).

The total cooling load (sensible plus latent) may be estimated by applying the latent factor (LF) from Figure 1. For a design humidity ratio of 0.0136 lb vapor per lb dry air, LF = 1.15 for a house of medium construction. Hence, the total cooling load equals 1.15 × 22,605 or 26,000 Btu/h.

Most residential unitary equipment operates with a cooling load that has a latent factor of 1.3 or a sensible heat factor of 0.77. Therefore, to ensure that the unit is large enough, it should be selected based on the sensible cooling load and the unit sensible cooling capacity. For this example, the sensible cooling capacity should be equal to or greater than 22,605 Btu/h and the total capacity, about 1.3 × 22,605 or 29,400 Btu/h. Therefore, a nominal 30,000 Btu/h (2.5 ton) unit is acceptable. On the basis of total capacity, the unit is oversized less than 25%.

The supply air quantities can now be computed. Air should be supplied to each room on the basis of the room sensible cooling load

$$Q_{rm} = Q_{tot}\,(q_{rm}/q)$$

where

Q_{rm} = Q airflow to each room
Q_{tot} = total airflow rate, about 400 cfm per ton of total capacity
q_{rm} = room sensible cooling load
q = total sensible cooling load

Thus:

$$Q_{rm} = (1000/19{,}095)\, q_{rm}$$

If the living space in Example 1 had been a multifamily unit (assume that the north, south, and east walls are not exposed surfaces), the calculation procedure would be the same, except that Table 2 would have been used for the CLTDs and Table 4 for the GLFs. Assumptions regarding infiltration, ventilation, and appliance loads are different for smaller multifamily units.

HEATING LOAD

Calculating a residential heating load involves estimating the maximum probable heat loss of each room or space to be heated and the simultaneous maximum loss for the building, while maintaining a selected indoor air temperature during periods of design outdoor weather conditions. Heat losses are mainly:

- Transmission losses or heat transferred through the confining walls, glass, ceiling, floor, or other surfaces.
- Infiltration losses or energy required to warm outdoor air leaking in through cracks and crevices around doors and windows or through open doors and windows, and through porous building materials.

GENERAL PROCEDURE

To calculate a design heating load, prepare the following information about building design and weather data at design conditions.

1. Select outdoor design weather conditions: temperature, wind direction, and wind speed. Winter climatic data can be found in Chapter 24, or selected weather conditions and temperatures appropriate for the application may be used. Weather station may differ significantly from values in Chapter 24.
2. Select the indoor air temperature to be maintained in each space during design weather conditions.
3. Estimated temperatures in adjacent unheated spaces, attached garages and attics can be at the outdoor ambient temperature.
4. Select or compute heat transfer coefficients for outside walls and glass; for inside walls, nonbasement floors, and ceilings, if these are next to unheated spaces; and for the roof if it is next to heated spaces.
5. Determine the net area of outside wall, glass, and roof next to heated spaces, as well as any cold walls, floors, or ceilings next to unheated spaces. These determinations can be made from building plans or from the actual building, using inside dimensions.
6. Compute heat transmission losses for each kind of wall, glass, floor, ceiling, and roof in the building by multiplying the heat transfer coefficient in each case by the area of the surface and the temperature difference between indoor and outdoor air or adjacent lower temperature spaces.
7. Compute heat losses from basement or grade-level slab floors using the methods in this chapter.
8. Select unit values, and compute the energy associated with infiltration of cold air around outside doors, windows, porous building materials, and other openings. These unit values depend on the kind or width of crack, wind speed, and the temperature difference between indoor and outdoor air. An alternative method is to use air changes (see Chapter 23.)
9. When positive ventilation using outdoor air is provided by an air heating or air-conditioning unit, the energy required to warm the outdoor air to the space temperature must be provided by the unit. The principle for calculation of this load component is identical to that for infiltration. If mechanical exhaust from the space is provided in an amount equal to the outdoor air drawn in by the unit, the unit must also provide for natural infiltration losses. If no mechanical exhaust is used and the outdoor air supply equals or exceeds the amount of natural infiltration that can occur without ventilation, some reduction in infiltration may occur.
10. The sum of the coincidental transmission losses or heat transmitted through the confining walls, floor, ceiling, glass, and other surfaces, plus the energy associated with cold air entering by infiltration or the ventilation air required to replace mechanical exhaust, represents the total heating load.
11. Include the pickup loads that may be required in intermittently heated buildings using night thermostat setback. Pickup loads frequently require an increase in heating equipment capacity to bring the temperature of structure, air, and material contents to the specified temperature. See Figure 9.
12. Use materials and data in Chapter 22, 23, 24, and others as are appropriate to the calculations. See Table 12.

Table 12 Summary of Loads, Equations, and References for Calculating Design Heating Loads

Heating Load	Equation	Reference, Table, Description
Roofs, ceilings, walls, glass	$q = U A \Delta t$	Chapter 22, Tables 1, 2, and 4 Temperature difference between inside and outside design dry bulbs, Chapter 24. For temperatures in unheated spaces, see Equation (1); for attic temperatures, see Equation (2). Area calculated from plans
Walls below grade	$q = U A \Delta t$	See Table 14 Use Figure 6 to assist in determining Δt
Floors		
Above grade	$q = U A \Delta t$	For crawl space temperatures, see Equation (4)
On grade	$q = F_2 P \Delta t$	See Table 16 See Equation (6) Perimeter of slab
Below grade	$q = U A \Delta t$	Use Figure 6 to assist in determining Δt See Table 15
Infiltration and ventilation air		
Sensible	$q_s = 0.018\ Q\ \Delta t$	Volume of outdoor air entering building. See Chapter 23 for estimating methods for infiltration.
Latent	$q_l = 80.7\ Q\ \Delta W$	Humidity ratio difference, if humidification is to be added.

SELECTING HEATING DESIGN CONDITIONS

The ideal solution to a basic heating system design is a plant with a maximum output capacity equal to the heating load that develops with most severe local weather conditions. However, this solution is usually uneconomical. Weather records show that severe weather conditions do not repeat annually. If heating systems were designed for maximum weather conditions, excess capacity would exist during most of the system's operating life.

In many cases, an occasional failure of a heating plant to maintain a preselected indoor design temperature during brief periods of severe weather is not critical. However, the successful completion of some industrial or commercial processes may depend on close regulation of indoor temperatures. The specific requirements for each building should be carefully evaluated.

Before selecting an outdoor design temperature from Chapter 24, the designer should consider the following for residential buildings:

- Is the type of structure heavy, medium, or light?
- Is the structure insulated?
- Is the structure exposed to high wind?
- Is the load from infiltration or ventilation high?
- Is there more glass area than normal?
- During what part of the day will the structure be used?
- What is the nature of occupancy?
- Will there be long periods of operation at reduced indoor temperature?
- What is the amplitude between local maximum and minimum daily temperatures?
- Are there local conditions that cause significant variation from temperatures reported by the Weather Bureau?
- What auxiliary heating devices will be in the building?

Before selecting an outdoor design temperature, the designer must keep in mind that, if the outdoor to indoor design temperature difference is exceeded, the indoor temperature may fall, depending on the thermal mass of the structure and its contents and on whether or not the internal load was included in calculations and the duration of the cold period.

The effect of wind on the heating requirements of any building should be considered, because:

- Wind movement increases the heat transmission of walls, glass, and roof, affecting poorly insulated walls to a much greater extent than well-insulated walls.
- Wind materially increases the infiltration of cold air through cracks around doors and windows and even through building materials themselves (see Chapter 23).

Theoretically, on a design basis, the most unfavorable combination of temperature and wind speed should be chosen. A building may require more heat on a windy day with a moderately low outdoor temperature than on a quiet day with a much lower outdoor temperature. The worst combination of wind and temperature varies in different buildings, because wind speed has a greater effect on buildings with relatively high infiltration rates. The building heating load may be calculated for several combinations of temperature and wind speed on record and the worst combination selected; however, except for critical applications, designers generally find such a degree of refinement unnecessary. No correlation has been shown between the design temperatures in Chapter 24 and the simultaneous maximum wind speed. If a designer prefers the air change method for computing infiltration rates, such correlation is not important. Designers who use the crack method can use a leakage rate at a wind speed of 15 mph, unless local experience has established that other speeds are more appropriate. Abnormally high wind speeds may have an effect on infiltration and the U-value of the building components (see Chapter 20).

ASHRAE *Standard* 90A-80 suggests 72 °F as the indoor temperature for comfort heating design; however, this may vary depending on building use, type of occupancy, or code requirements. Chapter 8 defines the relation of temperature and human comfort.

ESTIMATING TEMPERATURES IN ADJACENT UNHEATED SPACES

Heat loss from heated rooms to unheated rooms or spaces must be based on the estimated or assumed temperature in such unheated spaces. This temperature will lie in the range between the indoor and outdoor temperatures. If the respective surface areas adjacent to the heated room and exposed to the outdoors are the same and if the heat transfer coefficients are equal, the temperature in the unheated space may be assumed equal to the mean of the indoor and outdoor design temperatures. If, however, the surface areas and coefficients are unequal, the temperature in the unheated space should be estimated by:

$$t_u = [t_i(A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.}) + t_o(60\rho c_p Q_o + A_aU_a + A_bU_b + A_cU_c + \text{etc.})] \div (A_1U_1 + A_2U_2 + A_3U_3 + \text{etc.} + 60\rho c_p Q_o + A_aU_a + A_bU_b + A_cU_c + \text{etc.}) \quad (1)$$

where

ρc_p = density times specific heat of air = 0.018 Btu/ft^3 · °F for standard air
t_u = temperature in unheated space, °F
t_i = indoor design temperature of heated room, °F
t_o = outdoor design temperature, °F
A_1, A_2, A_3, etc. = areas of surface of unheated space adjacent to heated space, ft^2
A_a, A_b, A_c, etc. = areas of surface of unheated space exposed to outdoors, ft^2
U_1, U_2, U_3, etc. = heat transfer coefficients of surfaces of A_1, A_2, A_3, etc., Btu/h · ft^2 · °F
U_a, U_b, U_c, etc. = heat transfer coefficients of surfaces of A_a, A_b, A_c, etc., Btu/h · ft^2 · °F
Q_o = rate of introduction of outside air into unheated space by infiltration and/or ventilation, cfm

Example 2. Calculate the temperature in an unheated space adjacent to a heated room with surface areas (A_1, A_2, and A_3) of 100, 120, and 140 ft^2 and overall heat transfer coefficients (U_1, U_2, and U_3) of 0.15, 0.20, and 0.25 Btu/h · ft^2 · °F, respectively. The surface areas of the unheated space exposed to the outdoors (A_a and A_b) are 100 and 140 ft^2, respectively, and the corresponding overall heat transfer coefficients are 0.10 and 0.30 Btu/h · ft^2 · °F. The sixth surface is on the ground and can be neglected for this example, as can the effect of introduction of outdoor air into the unheated space. Assume t_i = 70 °F and t_o = −10 °F.

Solution: Substituting into Equation (1)

$$t_u = [70(100 \times 0.15 + 120 \times 0.20 + 140 \times 0.25) + (-10)(100 \times 0.10 + 140 \times 0.30)] \div (100 \times 0.15 + 120 \times 0.20 + 140 \times 0.25 + 100 \times 0.10 + 140 \times 0.30)$$

$$t_u = 4660/126 = 37\,°\text{F}$$

Temperatures in unheated spaces with large glass areas and two or more surfaces exposed to the outdoors (such as sleeping porches and sun parlors) are generally assumed to be the same as that of the outdoors.

Attic Temperature

An attic is a space having an average distance of 1 ft or more between a ceiling and the underside of the roof. Estimating attic temperature is a special case of estimating temperature in an adjacent unheated space and can be done using

$$t_a = \frac{A_cU_ct_c + t_o(\rho c_p A_c Q_c + A_rU_r + A_wU_w + A_gU_g)}{A_c(U_c + \rho c_p Q_c) + A_rU_r + A_wU_w + A_gU_g} \quad (2)$$

where

ρc_p = air density times specific heat = 0.018 Btu/h · ft^3 · °F for standard air
t_a = attic temperature, °F
t_c = indoor temperature near top floor ceiling, °F
t_o = outdoor temperature, °F
A_c = area of ceiling, ft^2
A_r = area of roof, ft^2
A_w = area of net vertical attic wall surface, ft^2
A_g = area of attic glass, ft^2
U_c = heat transfer coefficient of ceiling, Btu/h · ft^2 · °F, based on surface conductance of 2.2 Btu/h · ft^2 · °F (upper surface, see Chapter 22); 2.2 = reciprocal of one-half the air space resistance
U_r = heat transfer coefficient of roof, Btu/h · ft^2 · °F, based on surface conductance of 2.2 Btu/h · ft^2 · °F (upper surface, see Chapter 22); 2.2 = reciprocal of one-half the air space resistance
U_w = heat transfer coefficient of vertical wall surface, Btu/h · ft^2 · °F
U_g = heat transfer coefficient of glass, Btu/h · ft^2 · °F
Q_c = rate of introduction of outside air into the attic space by ventilation per square foot of ceiling area, cfm/ft^2

Example 3. Calculate the temperature in an unheated attic assuming t_c = 70 °F; t_o = 10 °F; A_c = 1000 ft^2; A_r = 1200 ft^2; A_w = 100 ft^2; A_g = 10 ft^2; U_r = 0.50 Btu/h · ft^2 · °F; U_c = 0.40 Btu/h · ft^2 · °F; U_w = 0.30 Btu/h · ft^2 · °F; U_g = 1.13 Btu/h · ft^2 · °F; and Q_c = 0.5 cfm/ft^2.

Solution: Substituting these values into Equation (2):

$$t_a = [(1000 \times 0.40 \times 70) + 10(1.10 \times 1000 \times 0.5 + 1200 \times 0.50 + 100 \times 0.30 + 10 \times 1.13)] \div [1000(0.40 + 1.10 \times 0.5) + 1200 \times 0.50 + 100 \times 0.30 + 10 \times 1.13)]$$

$$t_a = 39{,}913/1591 = 25.1\,°\text{F}$$

Equation (2) includes the effect of air interchange that would take place through attic vents or louvers intended to preclude attic condensation. Test data from Joy *et al.* (1956), Joy (1958), and Rowley *et al.* (1940) indicate that a reduction in the temperature difference between attic air and outside air is linear, with attic ventilation rates between 0 and 0.5 cfm/ft^2 of the ceiling area. When attic ventilation meets the requirements in Chapter 23, 0.5 cfm/ft^2 of the approximate ventilation rate is within design conditions. This reduction in temperature difference affects the overall heat loss of a residence with an insulated ceiling by only 1 or 2%.

Equation (2) also does not consider factors such as heat exchange between chimney and attic or solar radiation to and from the roof. Because of these effects, attic temperatures are frequently higher than values calculated by using the equations. However, Equation (2) can be used to calculate attic temperature, because the resulting error is generally less than that introduced by neglecting the roof and assuming the attic temperature equal to the outdoor air temperature.

When relatively large louvers are installed (customary in southern states), the attic temperature is often assumed as the average between indoor and outdoor air temperatures.

For a shorter, approximate method of calculating heat losses through attics, the combined ceiling and roof coefficient may be used (see Chapter 22).

Ground Temperature

Ground temperatures assumed for estimating basement heat losses will differ for basement floors and walls. The temperatures under floors are generally higher than those adjacent to walls. This is discussed further in the section Basement Design Temperatures.

CALCULATING HEAT LOSS FROM CRAWL SPACES

A crawl space can be considered a half basement. To prevent ground moisture from evaporating and causing a condensation problem, sheets of vapor retardant (*e.g.*, polyethylene film) are used to cover the ground surface (see Chapter 21). Most codes require crawl spaces to be adequately vented all year round. However, venting the crawl space in the heating season causes substantial heat loss through the floor.

The space may be insulated in several ways; the crawl space ceiling (floor above the crawl space) can be insulated, or the perimeter wall can be insulated either on the outside or on the inside of the wall. If the floor above is insulated, the crawl space vents should be kept open, because the temperature of the crawl space is likely to be below the dew point of the indoor space. If the perimeter wall is insulated, the vents should be kept closed in the heating season and open the remainder of the year.

Crawl Space Temperature

The crawl space temperature depends on such factors as venting, heating ducts, and the heating plant. When the crawl space is well ventilated, its temperature is close to that of the ambient air temperature. When the crawl space vent is closed for the heating season, or if the space is used as a plenum (*i.e.*, part of the forced air heating system), the crawl space temperature approaches the indoor conditioned space. In the former case, the floor above the crawl space, the heating duct work, and the utility pipes should be insulated similar to the walls and ceiling of a house.

The following steady-state equation can be used to estimate the temperature of a crawl space.

$$q_f = q_p + q_g + q_a \tag{3}$$

where

q_f = heat loss through floor into crawl space, Btu/h
q_p = heat loss through foundation walls and sill box from crawl space, Btu/h
q_g = heat loss into ground, Btu/h
q_a = heat loss due to ventilation of crawl space, Btu/h

Latta and Boileau (1969) estimate the air exchange rate for an uninsulated basement at 0.67 air changes per hour under winter conditions. In more detail, Equation (3) can be repeated as

$$U_f A_f (t_i - t_c) = U_p A_p (t_c - t_o) + U_g A_g (t_c - t_g) + 0.67 (H_c V_c)(t_c - t_o) \tag{4}$$

where

t_i = indoor temperature, *i.e.*, air above ceiling of crawl space, °F
t_o = outdoor temperature, °F
t_g = ground temperature (constant), °F
t_c = crawl space temperature, °F
A_f = area of floor above, ft^2
A_p = area of perimeter, exposed foundation wall plus sill box, ft^2
A_g = area of ground below ($A_f = A_g$), ft^2
U_f = average heat transfer coefficient through floor, Btu/h·ft^2·°F
U_g = average heat transfer coefficient through ground (horizontal air film and 10 ft of soil), Btu/h·ft^2·°F
U_p = combined heat transfer coefficient of sill box and foundation wall (both above and below grade), Btu/h·ft^2·°F
V_c = volume of crawl space, ft^3
H_c = volumetric heat capacity of air = 0.018 Btu/ft^3·°F
0.67 = assumed air exchange rate, volume/hour

Example 4. A crawl space of 1200 ft^2, with a 140-ft perimeter, is considered. The construction of the perimeter wall is shown in Figure 3. The indoor, outdoor, and the deep-down ground temperatures are 70, 10, and 50°F, respectively. Estimate the heat loss and crawl space temperature with and without insulation. The heat transmission coefficient (U-factor) for each component is indicated in Table 13.

Solution: Three cases are examined.

Case A. This base case is a vented and uninsulated crawl space. The crawl space temperature approaches that of the outdoors, 10°F, and the heat loss is 0.25 × 1200(70 − 10) = 18,000 Btu/h.

Case B. The crawl space is vented. The floor above is insulated with an R = 11 blanket; no insulation on the perimeter. The temperature of the crawl space approaches that of the outdoors, 10°F. The heat loss is calculated as

$$q_f - 1200(70 - 10) = 5472 \text{ Btu/h}$$

Table 13 Estimated U-Values for Insulated and Uninsulated Crawl Spaces

Component	Uninsulated Btu/h·°F per ft of Perimeter	Insulated[a] Btu/h·°F per ft of Perimeter
16-in. exposed concrete blocks	0.7	0.18
7.5-in. sill box	0.188	0.071
1st 12-in. block wall below grade	0.355	0.127
2nd 12-in. block wall below grade	0.22	0.14
3rd 12-in. block wall below grade	0.133	0.1
Total for perimeter wall	1.6	0.62
	Btu h·ft^2·°F	**Btu h·ft^2·°F**
Ground	0.077	0.077
Floor above crawl space	0.25	0.076[a]

[a]Perimeter walls are insulated with R = 5.4; the floor is insulated with R = 11 blanket or batts.

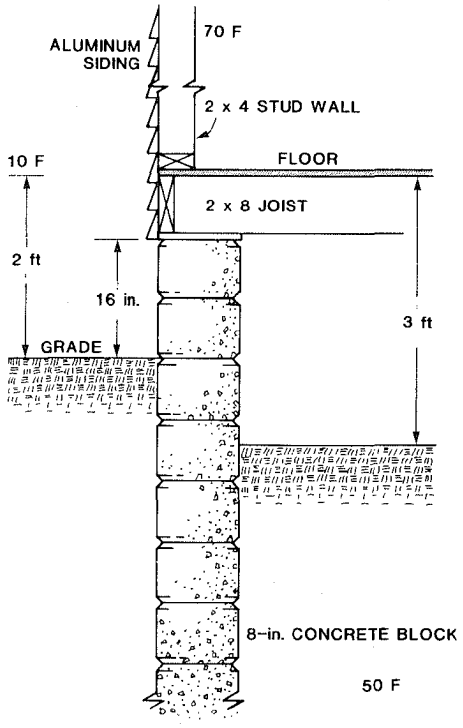

Fig. 3 Uninsulated Crawl Space

Case C. The crawl space is not vented during the heating season. The floor above is not insulated, but the perimeter wall is insulated with R = 5.4 down to 3 ft below grade.

$$q_f = 1200 \times 0.25(70 - t_c)$$
$$q_p = 140 \times 0.62(t_c - 10)$$
$$q_g = 1200 \times 0.077(t_c - 50)$$
$$q_a = 1200 \times 3 \times 0.67 \times 0.018(t_c - 10)$$

The crawl space temperature is solved using Equation (4), t_c = 51.5°F. The heat loss is 5530 Btu/h.

The results show that base case A can potentially lose the most heat. However, when the floor above is insulated, the crawl space must be vented to eliminate any condensation potential, and the heating duct work and utility pipeline in the crawl space must be adequately insulated. When the perimeter is insulated, the vents must be closed during the heating season and opened for the rest of the year; the heating duct work and utility pipeline do not need insulation.

Case	Venting	Insulation	Heat Loss through Floor Above, Btu/h	Temperature of Crawl Space, °F
Base	Yes	None	18,000	10
A	Yes	R = 11 on floor above	5,470	10
B	No	R = 5.4 on perimeter wall	5,530	51.5

CALCULATING TRANSMISSION HEAT LOSS

Steady-state heat loss by conduction and convection heat transfer through any surface is:

$$q = AU(t_i - t_o) \quad (5)$$

where

q = heat transfer through wall, roof, ceiling, floor, Btu/h
A = area of wall, glass, roof, ceiling, floor, or other exposed surface, ft²
U = air-to-air heat transfer coefficient, Btu/h·ft²·°F
t_i = indoor air temperature near surface involved, °F
t_o = outdoor air temperature, or temperature of adjacent unheated space, °F

Example 5. Calculate the transmission loss through an 8-in. brick wall having an area of 150 ft², if the indoor temperature t_i is 70°F, and the outdoor temperature t_o is −10°F.

Solution: The overall heat transfer coefficient U of a plain 8-in. brick wall is 0.41 Btu/h·ft²·°F. Substituting into Equation (5):

$$q = 150 \times 0.41\,[70 - (-10)] = 4920 \text{ Btu/h}$$

Through Ceiling and Roof

Transmission heat loss through top floor ceilings, attics, and roofs may be estimated by either of two methods:

1. Substitute in Equation (5) the ceiling area A, the indoor/outdoor temperature difference $(t_i - t_o)$, and the proper U-value:

   Flat roofs. Use appropriate coefficients in Equation (2), as outlined in Chapter 22, if side walls extend appreciably above the ceiling or the floor below.

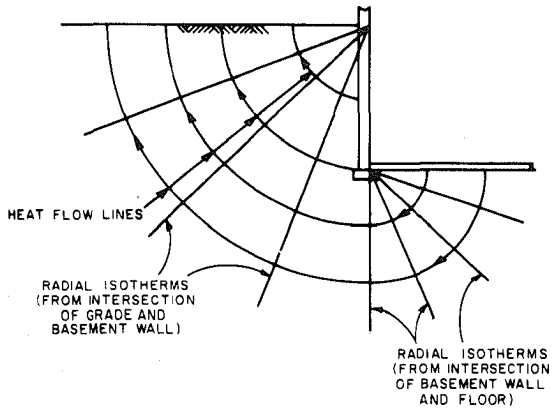
   Pitched roofs. Calculate the combined roof and ceiling coefficient by means outlined in Chapter 22.

2. For *pitched roofs*, estimate the attic temperature (based on the indoor and outdoor design temperatures) using Equation (2), and substitute for t_o in Equation (5), obtaining the value of t_a, together with the ceiling area A and the ceiling U-value. Attic temperatures do not need to be calculated for *flat roofs*, as the ceiling-roof heat loss can be determined as suggested in (1) above.

From the Basement

The basement interior is considered conditioned space if a minimum of 10°F is maintained over the heating season. In many instances, the house heating plant, water heater, and heating ducts are in the basement, so it remains at or above 50°F.

The heat transmission from the below-grade portion of the basement wall to the ambient air cannot be estimated by simple, one-dimensional heat conduction. In fact, field measurement of an uninsulated basement by Latta and Boileau (1969) showed that the isotherms near the wall are not parallel lines but closer to radial lines centered at the intersection of the grade line and the wall. Therefore, heat flow paths approximately follow a set of concentric circular patterns (Figure 4).



HEAT FLOW LINES
RADIAL ISOTHERMS (FROM INTERSECTION OF GRADE AND BASEMENT WALL)
RADIAL ISOTHERMS (FROM INTERSECTION OF BASEMENT WALL AND FLOOR)

Fig. 4 Heat Flow from Basement

Such heat flow paths are altered when insulation is added to the wall or floor. An extreme case would be no heat loss from the basement wall and floor, *i.e.*, infinite insulation applied to the wall and floor. In this case, the isotherms would be horizontal lines parallel to the grade line, and the heat flow would be vertical. When finite insulation or partial insulation is applied to the wall and floor, the heat flow paths take shapes somewhere between the circular and vertical lines (Figure 5).

Through Basement Walls

Houghten *et al.* (1942) observed nonuniform heat flux across the basement wall with respect to the depth of the wall, because each heat flow path contains a different thermal resistance. For a basement wall that has its top portion exposed to ambient air, heat may be conducted vertically through the concrete wall and dissipated to the ambient from the top portion of the wall (Wang 1979, Bligh *et al.* 1978). Under certain conditions, this vertical heat flux becomes significant and should not be ignored.

Once the heat paths are known or assumed, a steady-state analysis can calculate the overall heat transmission coefficient for each segment of the basement wall. Referring to Figures 4 and 5, the total thermal resistance for each depth increment of the basement wall can be found by summing the thermal resistances along each heat flow path. Based on these resistances, the heat loss at each depth increment can be estimated for a unit temperature difference between the basement and the average mean winter temperature. Table 14 lists such heat loss values at different depths for an uninsulated and insulated concrete wall (Latta and Boileau 1969). Also listed are the lengths of the heat flow path through the soil (circular path). The conductivity of the soil was assumed to be 9.6 Btu/h·ft²·°F.

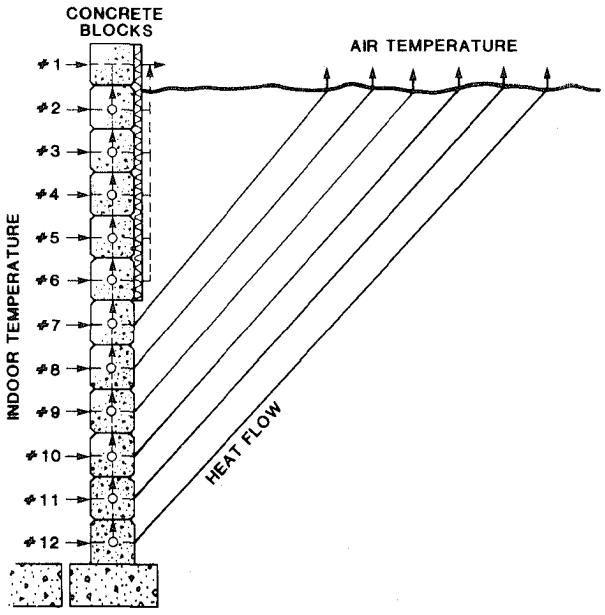


Fig. 5 Heat Flow Path for Partially Insulated Basement Wall

Table 14 Heat Loss Below Grade in Basement Walls

Depth, ft	Path Length through Soil, ft	Heat Loss, Btu/h·ft²·°F							
		Uninsulated		R = 4.17		R = 8.34		R = 12.5	
0 to 1	0.68	0.410		0.152		0.093		0.067	
1 to 2	2.27	0.222	0.632	0.116	0.268	0.079	0.172	0.059	0.126
2 to 3	3.88	0.155	0.787	0.094	0.362	0.068	0.240	0.053	0.179
3 to 4	5.52	0.119	0.906	0.079	0.441	0.060	0.300	0.048	0.227
4 to 5	7.05	0.096	1.002	0.069	0.510	0.053	0.353	0.044	0.271
5 to 6	8.65	0.079	1.081	0.060	0.570	0.048	0.401	0.040	0.311
6 to 7	10.28	0.069	1.150	0.054	0.624	0.044	0.445	0.037	0.348

Through Basement Floors

The same steady-state design used for the basement wall can be applied to the basement floor, except that the length of the heat flow path is longer (see Figure 4). Thus, the heat loss through the basement floor is much smaller than that from the wall. Therefore, an average value for the heat loss through the basement floor can be multiplied by the floor area to give total heat loss from the floor. Table 15 lists typical values.

Basement Design Temperatures

Although internal design temperature is given by basement air temperature, none of the usual external design air temperatures apply because of the heat capacity of the soil. However, ground surface temperature fluctuates about a mean value by an amplitude A, which varies with geographic location and surface cover. Therefore, suitable external design temperatures can be obtained by subtracting A for the location from the mean winter air temperature t_a. Values for t_a can be obtained from meteorological records, and A can be estimated from the map in Figure 6. This map is part of one prepared by Chang (1958) giving annual ranges in ground temperature at a depth of 4 in.

Example 6. Consider a basement 28 ft wide by 30 ft long sunk 6 ft below grade, with R = 8.34 insulation applied to the top 2 ft of the wall below grade. Assume an internal air temperature of 70°F and an external design temperature ($t_a - A$) of 20°F.

Solution:

Wall (using Table 14)

First foot below grade	0.093 Btu/h·ft·°F
Second foot below grade	0.079 Btu/h·ft·°F
Third foot below grade	0.155 Btu/h·ft·°F
Fourth foot below grade	0.119 Btu/h·ft·°F
Fifth foot below grade	0.096 Btu/h·ft·°F
Sixth foot below grade	0.079 Btu/h·ft·°F
Total per foot length of wall	0.621 Btu/h·ft·°F
Basement perimeter	2(28 + 30) = 116 ft
Total wall heat loss	0.62 × 116 = 72 Btu/h·°F

Floor (using Table 4)

Average heat loss per ft²	0.025 Btu/h·°F
Floor area 28 × 30	840 ft²
Total floor heat loss	0.025 × 840 = 21 Btu/h·°F

Total

Total basement heat loss below grade	72 + 21 = 93 Btu/h·°F
Design temperature difference	70 − 20 = 50°F
Maximum rate of heat loss from below-grade basement	93 × 50 = 4650 Btu/h

Table 15 Heat Loss through Basement Floors, Btu/h·ft²·°F

Depth of Foundation Wall Below Grade, ft	Shortest Width of House, ft			
	20	24	28	32
5	0.032	0.029	0.026	0.023
6	0.030	0.027	0.025	0.022
7	0.029	0.026	0.023	0.021

Note: $\Delta F = (t_a - A)$

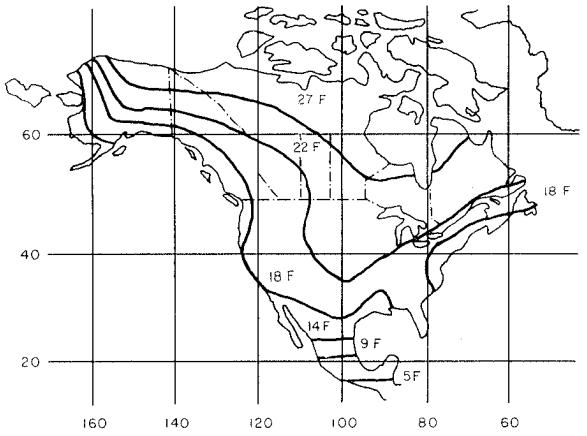

Fig. 6 Lines of Constant Amplitude

If a basement is completely below grade and unheated, its temperature ranges between that in the rooms above and that of the ground. Basement windows lower the basement temperature when it is cold outdoors, and heat given off by the heating plant increases the basement temperature. The exact basement temperature is indeterminate if the basement is not heated. In general, heat from the heating plant sufficiently warms the air near the basement ceiling to make an allowance unnecessary for floor heat loss from rooms located over the basement.

Transient Calculations, Basement Walls

The heat loss from basement walls can be estimated more accurately with a finite element or finite difference computer program by transient simulations (Wang 1979, Bligh *et al.* 1978). The solution is in the form of heat loss over time, which can be converted to an average U-value. This approach also offers the possibility for estimating the depth below grade to which insulation is economical. Direct and indirect evidence of hollow concrete block walls shows a convective path existing within the blocks, vertically along the wall (Harrje *et al.* 1979). Therefore, insulation should be arranged to reduce this convective heat transfer.

Peony *et al.* (1979) showed that the dynamic thermal performance of a masonry wall is better when insulation is placed on the exterior. Moreover, transient simulation showed that insulation is more effective when it is placed on the exterior side of the basement wall. Depending on the exposed portion of the block wall and the temperature difference between indoor and outdoor air, exterior application can be 10 to 20% more efficient than a corresponding interior application. However, such exterior application must be installed properly to maintain its integrity.

Calculating Transmission Heat Loss from Floor Slabs

Concrete slab floors are (1) unheated, relying for warmth on heat delivered above floor level by the heating system, and (2) heated, containing heated pipes or ducts that constitute a radiant slab or portion of it for complete or partial heating of the house.

The perimeter insulation of a slab-on-grade floor is quite important for comfort and energy conservation. In unheated slab floors, the floor edge must be insulated to keep the floor warm. Downdrafts from windows or exposed walls can create pools of chilly air over considerable areas of the floor. In heated slab floors, the floor edge must be insulated to prevent excessive heat loss from the heating pipe or duct embedded in the floor or from the baseboard heater.

Wang (1979) and Bligh *et al.* (1978) found that heat loss from an unheated concrete slab floor is mostly through the perimeter rather than through the floor and into the ground. Total heat loss is more nearly proportional to the length of the perimeter than to the area of the floor, and it can be estimated by the following equation for both unheated and heated slab floors:

$$q = F_2 P (t_i - t_o) \quad (6)$$

where

q = heat loss through perimeter, Btu/h
F_2 = heat loss coefficient per foot of perimeter (see Table 5), Btu/(h·°F·ft)
P = perimeter or exposed edge of floor, ft
t_i = indoor temperature, °F. (For the heated slab, t_i is the weighted average heating duct or pipe temperature.)
t_o = outdoor temperature, °F

Vertical "I"-shape systems are used to insulate slab floor perimeters. In the "I" system, the insulation is placed vertically next to the exposed slab edge, extending downward below grade, as shown in Figure 7.

Breaks or joints must be avoided when the insulation is installed; otherwise, local thermal bridges can be formed, and the overall efficiency of the insulation is reduced.

Transient Calculations, Floor Slabs

Figure 8 shows four basic slab-on-grade constructions analyzed with a finite element computer program by Wang (1979). Figures 8a-c represent unheated slabs; Figure 8d can be considered a heated slab. Each was investigated with and without insulation of $R = 5.4$ under three climate conditions (7433, 5350, and 2950 degree days). Table 16 lists results in terms of heat loss coefficient F_2, based on degree days.

Table 16 shows that the heat loss coefficient F_2 is sensitive to both construction and insulation. The reverse loss, or heat loss into the ground and outward through the edges of the slab and foundation wall, is significant when heating pipes or ducts or when baseboard heaters are placed near the slab perimeters. To prevent reverse loss, the designer may find it advantageous to use perimeter insulation even in warmer climates. For severe winter regions (above 6000 degree days), the insulation value should be increased to $R > 10$.

Figure 8a shows that this construction benefits from the wall insulation between block and brick; the insulation is extended roughly 16 in. below the slab floor. Without this wall insulation, the heat loss coefficient F_2 would be close to that of the 4-in. block wall construction (Figure 8b). Table 16 can be used to estimate F_2 under different degree days of heating season weather.

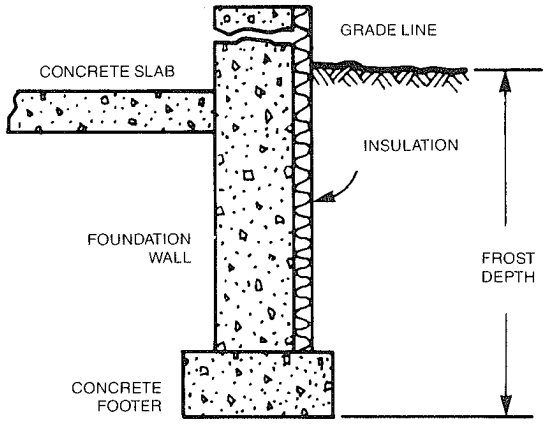

Fig. 7 "I" Shape or Vertical Insulation System

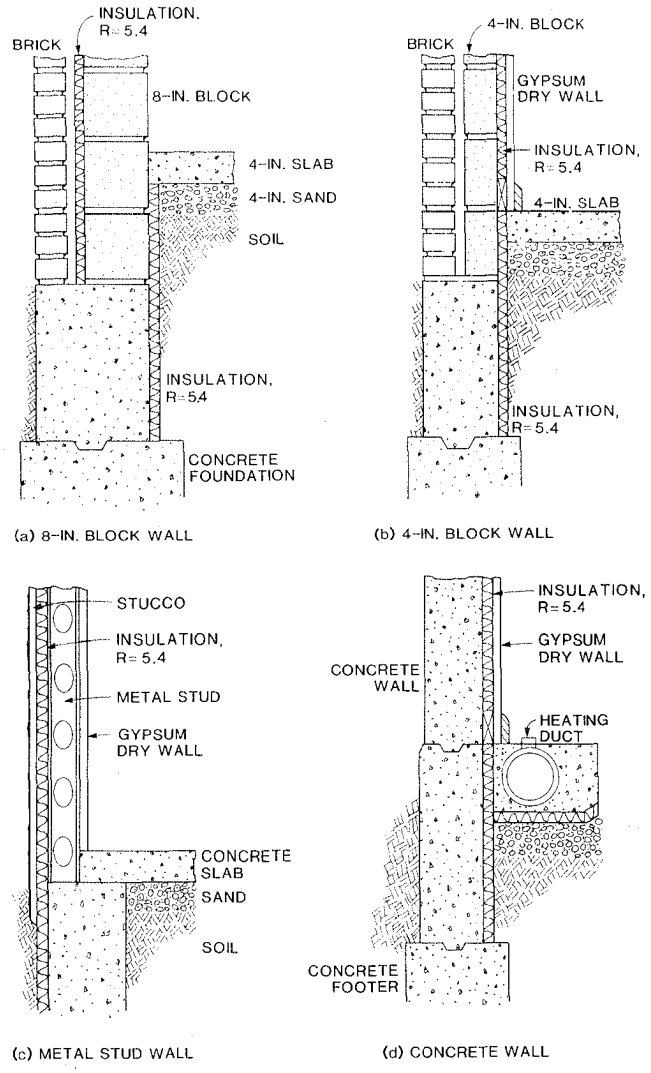

Fig. 8 Slab-on-Grade Foundation Insulation

Table 16 Heat Loss Coefficient F_2 of Slab Floor Construction, Btu/h · °F per ft of Perimeter

Construction	Insulation[a]	Degree Days (65 °F Base) 2950	5350	7433
8-in. block wall, brick facing	Uninsulated	0.62	0.68	0.72
	R = 5.4 from edge to footer	0.48	0.50	0.56
4-in block wall, brick facing	Uninsulated	0.80	0.84	0.93
	R = 5.4 from edge to footer	0.47	0.49	0.54
Metal stud wall, stucco	Uninsulated	1.15	1.20	1.34
	R = 5.4 from edge to footer	0.51	0.53	0.58
Poured concrete wall with duct near perimeter[b]	Uninsulated	1.84	2.12	2.73
	R = 5.4 from edge to footer, 3 ft under floor	0.64	0.72	0.90

[a]R-value units in °F · ft² · h/Btu · in.
[b]Weighted average temperature of the heating duct was assumed at 110 °F during the heating season (outdoor air temperature less than 65 °F).

CALCULATING INFILTRATION HEAT LOSS

Infiltration of outside air causes both *sensible* and *latent* heat loss. The energy required to raise the temperature of outdoor infiltrating air to indoor air temperature is the sensible component. The energy associated with net loss of moisture from the space is the latent component. Infiltration is discussed in detail in Chapter 23.

Sensible Heat Loss

The energy required to warm outdoor air entering by infiltration to the temperature of the room is given by:

$$q_s = c_p Q\rho(t_i - t_o) \tag{7}$$

where

q_s = heat flow required to raise temperature of air leaking into building from t_o to t_i, Btu/h
c_p = specific heat of air, Btu/lb · °F
Q = volume of outdoor air entering building, ft³/h
ρ = density of air at temperature t_o, lb/ft³

Using standard air, Q = 0.075 lb/ft³, and c_p = 0.24, Equation (7) reduces to:

$$q_s = 0.018\, Q(t_i - t_o) \tag{8}$$

The volume Q of outdoor air entering depends on wind speed and direction, width of cracks or size of openings, type of openings, and other factors explained in Chapter 23. The two methods used to obtain the quantity of infiltration air are the *crack length* and the *air change*. Louvers and doors and the direction they face, as well as any other factors that affect infiltration, may need to be considered.

Latent Heat Loss

When moisture must be added to the indoor air to maintain winter comfort conditions, the energy needed to evaporate an amount of water equivalent to what is lost by infiltration (latent component of infiltration heat loss) must be determined. This energy may be calculated by:

$$q_l = Q\rho(W_i - W_o)h_{fg} \tag{9}$$

where

q_l = heat flow required to increase moisture content of air leakage into building from W_o to W_i, Btu/h
Q = volume of outdoor air entering building, ft³/h
ρ = density of air at temperature t_i, lb/ft³
W_i = humidity ratio of indoor air, $lb/lb_{dry\ air}$
W_o = humidity ratio of outdoor air, $lb/lb_{dry\ air}$
h_{fg} = latent heat of vapor at t_i, Btu/lb

If the latent heat of vapor h_{fg} is 1076 Btu/lb, and the air density is 0.075 lb/ft³, Equation (7) reduces to:

$$q_l = 80.7\, Q(W_i - W_o) \tag{10}$$

Crack Length Method

For designers who prefer the crack method, the basis of calculation is: the amount of crack used for computing the infiltration heat loss should not be less than one-half the total length of crack in the outside walls of the room. In a building without partitions, air entering through cracks on the windward side must leave through cracks on the leeward side. Therefore, one-half the total crack for each side and end of the building is used for calculation. In a room with one exposed wall, all the crack is used. With two, three, or four exposed walls, the wall with the crack that will result in the greatest air leakage or at least one-half the total crack is used, whichever is greater.

In residences, total infiltration loss of the house is generally considered equal to the sum of infiltration losses of the various rooms.

But, at any given time, infiltration takes place only on the windward side or sides and not on the leeward. Therefore, for determining total heat requirements of larger buildings, it is more accurate to base total infiltration loss on the wall with the most total crack or at least half the total crack in the building, whichever is greater. When the crack method is used for estimating leakage, rather than Equation (8), the heat loss in terms of the crack length may be expressed as

$$q_s = 0.018BL(t_i - t_o) \quad (11)$$

and

$$q_l = 80.7BL(W_i - W_o) \quad (12)$$

where

B = air leakage for wind velocity and type of window or door crack involved, ft³/h per foot of crack
L = length of window or door crack to be considered, ft

Air Change Method

Some designers base infiltration on an estimated number of air changes rather than the length of window cracks. The number of air changes given in Chapter 23 should be considered only as a guide. When calculating infiltration losses by the air change method, Equations (8) and (10) can be used by substituting for V the volume of the room multiplied by the number of air changes.

Exposure Factors

Some designers use empirical *exposure* factors to increase calculated heat loss of rooms or spaces on the side(s) of the building exposed to prevailing winds. However, exposure factors are not needed with the method of calculating heat loss described in this chapter. Instead, they may be (1) regarded as safety factors for the rooms or spaces exposed to prevailing winds, to allow for additional capacity for these spaces, or (2) used to balance the radiation, particularly in the case of multistory buildings. Tall buildings may have severe infiltration heat losses, induced by stack effect, that require special analysis. Although a 15% exposure allowance is often assumed, the actual allowance, if any, is largely a matter of experience and judgment; no test data are available from which to develop rules for the many conditions encountered.

PICK-UP LOAD

For intermittently heated buildings, or in the case of night thermostat setback, additional heat is required to raise the temperature of air, building materials, and material contents of a building to the specified indoor temperature. The pick-up load, which is the rate at which this additional heat must be supplied, depends on the heat capacity of the structure and its material contents and the time in which these are to be heated.

Relatively little information on pick-up load exists; however, some early work by Smith (1941, 1942) addressed pick-up loads for buildings heated only occasionally, such as auditoriums and churches. Nelson and MacArthur (1978) studied the relationship between thermostat setback, furnace capacity, and recovery time. Based on this limited information, the following design guidelines are offered.

Because design outdoor temperatures generally provide a substantial margin for outdoor temperatures typically experienced during operating hours, many engineers make no allowance for this additional heat in most buildings. However, if a minimum safety factor is to be used, the additional heat should be computed and allowed for, as conditions require. In the case of intermittently heated buildings, an additional 10% capacity should be provided.

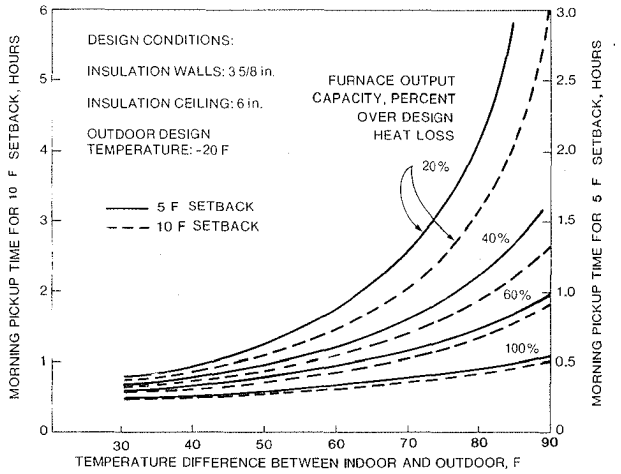

Fig. 9 Operating Time of Furnace Required to Pick Up Space Temperature Following 5 and 10°F Night Setback for Various Furnace Sizes

In buildings with setback-type thermostats, the furnace must be oversized to allow for reestablishing the space temperature in an acceptable time. The amount of oversizing depends on many factors, such as the amount of setback, inside-to-outside temperature difference, building construction and acceptable pick-up time. Figure 9 indicates this relationship for a particular residence. As a general rule for residences, a 10°F night setback requires 40% oversizing for acceptable pick-up time and minimum energy requirements (Nelson and MacArthur 1978). For smaller setback, the oversizing can be proportionally less. If daytime as well as night setback is practiced, oversizing of up to 60% is warranted.

Cooling Load by Time Averaging 26.58
Example Cooling Load Calculation Using TETD/TA 26.59

THIS chapter presents three methods of calculating air-conditioning cooling load for sizing cooling equipment and a general procedure for calculating heating load, for nonresidential applications. In addition, the fundamental principles for calculating heating loads are presented as a counterpart to cooling load calculation. For residential applicaitons, consult Chapter 25. For information on cooling and/or heating equipment energy use, consult Chapter 28.

The heat balance approach is a fundamental concept in calculating cooling loads. While generally cumbersome for widespread or routine use, this underlying concept is the basis for each of the three simplified procedures outlined for varying purposes.

The cooling calculation procedure most closely approximating the heat balance concept is the transfer function method (TFM), first introduced in the 1972 ASHRAE *Handbook of Fundamentals*. This computer-based procedure takes place in two steps, first establishing the heat gain from all sources and then determining the conversion of such heat gain into cooling load. Developed as an hour-by-hour calculation procedure oriented to simulate annual energy use, its normalizing characteristics make it particularly appropriate for that application.

A simplified version of the TFM, which can be used with certain types of buildings for which application data are available, was presented in the 1977 ASHRAE *Handbook of Fundamentals*. This one-step procedure uses cooling load temperature differences (CLTD), solar cooling load factors (SCL), and internal cooling load factors (CLF), to calculate cooling loads as an approximation of the TFM. Where applicable, this method may be suitable for hand calculation use.

An alternative simplification of the heat balance technique uses total equivalent temperature differential values and a system of time-averaging (TETD/TA) to calculate cooling loads. Also a computer-based, two-step procedure (heat gain, then cooling load), first introduced in the 1967 ASHRAE *Handbook of Fundamentals*, this method gives valid broad-range results to experienced users.

COOLING LOAD PRINCIPLES

The variables affecting cooling load calculations are numerous, often difficult to define precisely, and always intricately interrelated. Many cooling load components vary in magnitude over a wide range during a 24-h period. Since these cyclic changes in load components are often not in phase with each other, each must be analyzed to establish the resultant maximum cooling load for a building or zone. A zoned system (a system of conditioning equipment serving several independent areas, each with its own temperature control) need recognize no greater total cooling load capacity than the largest hourly summary of simultaneous zone loads throughout a design day; however, it must handle the peak cooling load for each zone at its individual peak hour. At certain times of the day during the heating or intermediate seasons, some zones may require heating while others require cooling.

Calculation accuracy. The concept of determining the cooling load for a given building must be kept in perspective. A proper cooling load calculation gives values adequate for proper performance. Variation in the heat transmission coefficients of typical building materials and composite assemblies, the differing motivations and skills of those who physically construct the building, and the manner in which the building is actually operated are some of the variables that make a numerically precise calculation impossible. While the designer uses reasonable procedures to account for these factors, the calculation can never be more than a good estimate of the actual cooling load.

Heat flow rates. In air-conditioning design, four related heat flow rates, each of which varies with time, must be differentiated: (1) space heat gain, (2) space cooling load, (3) space heat extraction rate, and (4) cooling coil load.

Space heat gain. This instantaneous rate of heat gain is the rate at which heat enters into and/or is generated within a space at a given instant. Heat gain is classified by (1) the mode in which it enters the space and (2) whether it is a sensible or latent gain.

Mode of entry. The modes of heat gain may be as (1) solar radiation through transparent surfaces; (2) heat conduction through exterior walls and roofs; (3) heat conduction through interior partitions, ceilings, and floors; (4) heat generated within the space by occupants, lights, and appliances; (5) energy transfer as a result of ventilation and infiltration of outdoor air; or (6) miscellaneous heat gains.

Sensible or latent heat. Sensible heat gain is directly added to the conditioned space by conduction, convection, and/or radiation. Latent heat gain occurs when moisture is added to the space (*e.g.*, from vapor emitted by occupants and equipment). To maintain a constant humidity ratio, water vapor must condense on

The preparation of this chapter is assigned to TC 4.1, Load Calculation Data and Procedures.

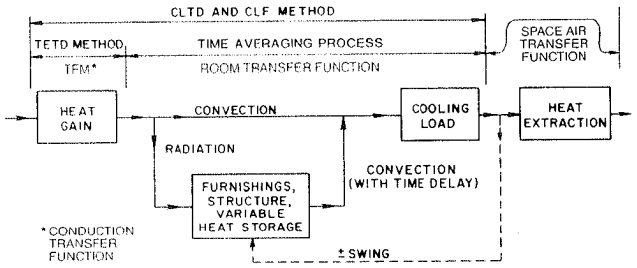

Fig. 1 Origin of Difference between Magnitude of Instantaneous Heat Gain and Instantaneous Cooling Load

cooling apparatus at a rate equal to its rate of addition into the space. The amount of energy required to offset the latent heat gain essentially equals the product of the rate of condensation and the latent heat of condensation. In selecting cooling apparatus, it is necessary to distinguish between sensible and latent heat gain. Every cooling apparatus has a maximum sensible heat removal capacity and a maximum latent heat removal capacity for particular operating conditions.

Space cooling load. This is the rate at which heat must be removed from the space to maintain a constant space air temperature. The sum of all space instantaneous heat gains at any given time does not necessarily (or even frequently) equal the cooling load for the space at that same time.

Radiant heat gain. Space heat gain by radiation is not immediately converted into cooling load. Radiant energy must first be absorbed by the surfaces that enclose the space (walls, floor, and ceiling) and the objects in the space (furniture, etc.). As soon as these surfaces and objects become warmer than the space air, some of their heat is transferred to the air in the space by convection. The composite heat storage capacity of these surfaces and objects determines the rate at which their respective surface temperatures increase for a given radiant input, and thus governs the relationship between the radiant portion of heat gain and its corresponding part of the space cooling load (Figure 1). The thermal storage effect is critically important in differentiating between instantaneous heat gain for a given space and its cooling load for that moment. Predicting the nature and magnitude of this elusive phenomenon in order to estimate a realistic cooling load for a particular combination of circumstances has long been a subject of major interest to design engineers. The bibliography lists some of the early work on the subject.

Space Heat Extraction Rate

The rate at which heat is removed from the conditioned space equals the space cooling load only to the degree that room air temperature is held constant. In conjunction with intermittent operation of the cooling equipment, the control system characteristics usually permit a minor cyclic variation or swing in room temperature. Therefore, a proper simulation of the control system gives a more realistic value of energy removal over a fixed time period than using the values of the space cooling load. This concept is primarily important for estimating energy use over time (see Chapter 28); however, it is not needed to calculate design peak cooling load for equipment selection. Space heat extraction rate calculation is discussed later in this chapter; see also Mitalas (1972).

Cooling Coil Load

The rate at which energy is removed at the cooling coil that serves one or more conditioned spaces equals the sum of the instantaneous space cooling loads (or space heat extraction rate if it is assumed that the space temperature does not vary) for all the spaces served by the coil, plus any external loads. Such external loads include heat gain by the distribution system between the individual spaces and the cooling equipment, and outdoor air heat and moisture introduced into the distribution system through the cooling equipment.

SPACE COOLING LOAD CALCULATION TECHNIQUES

Heat Balance Fundamentals

The calculation of cooling load for a space involves calculating a surface-by-surface conductive, convective, and radiative heat balance for each room surface and a convective heat balance for the room air. Sometimes called "the exact solution," these principles form the foundation for all other methods described in this chapter.

To calculate space cooling load directly by heat balance procedures requires a laborious solution of energy balance equations involving the space air, surrounding walls and windows, infiltration and ventilation air, and internal energy sources. To demonstrate the calculation principle, consider a sample room enclosed by four walls, a ceiling, and a floor, with infiltration air and normal internal energy sources. The calculations that govern energy exchange at each inside surface at a given time are:

$$q_{i,\theta} = [h_{ci}(t_{a,\theta} - t_{i,\theta}) + \sum_{j=1 \neq i}^{m} g_{ij}(t_{j,\theta} - t_{i,\theta})]\, A_i + RS_{i,\theta} + RL_{i,\theta} + RE_{i,\theta} \text{ for } i = 1, 2, 3, 4, 5, 6 \quad (1)$$

where

m = number of surfaces in room (6 in this case)
$q_{i,\theta}$ = rate of heat conducted into surface i at inside surface at time θ
A_i = area of surface i
h_{ci} = convective heat transfer coefficient at interior surface i
g_{ij} = radiation heat transfer factor between interior surface i and interior surface j
$t_{a,\theta}$ = inside air temperature at time θ
$t_{i,\theta}$ = average temperature of interior surface i at time θ
$RS_{i,\theta}$ = rate of solar energy coming through windows and absorbed by surface i at time θ
$RL_{i,\theta}$ = rate of heat radiated from lights and absorbed by surface i at time θ
$RE_{i,\theta}$ = rate of heat radiated from equipment and occupants and absorbed by surface i at time θ

Conduction transfer functions. The equations governing conduction within the six surfaces cannot be solved independently of Equation (1), since the energy exchanges occurring within the room affect the inside surface conditions, in turn affecting the internal conduction. Consequently, the above mentioned six formulations of Equation (1) must be solved simultaneously with the governing equations of conduction within the six surfaces in order to calculate the space cooling load. Typically, these equations are formulated as conduction transfer functions in the form

$$q_{in,\theta} = \sum_{m=1}^{M} Y_{k,m}\, t_{o,\theta-m+1} - \sum_{m=1}^{M} Z_{k,m}\, t_{in,\theta-m+1} + \sum_{m=1}^{m} F_m q_{in,\theta-m} \quad (2)$$

where

in = inside surface subscript
k = order of CTF
m = time index variable
M = number of nonzero CTF values
o = outside surface subscript

t = temperature
θ = time
x = exterior CTF values
Y = cross CTF values
Z = interior CTF values
F_m = flux history coefficients

Space air energy balance. Note that the interior surface temperature, $t_{i,\theta}$ in Equation (1) and $t_{in,\theta}$ in Equation (2), requires simultaneous solution. In addition, Equation (3) representing an energy balance on the space air must also be solved simultaneously

$$Q_{L,\theta} = \left[\sum_{i=1}^{6} h_{ci} (t_{i,\theta} - t_{a,\theta}) \right] A_i + {}_{\sigma} CV_{L,t} (t_{o,\theta} - t_{a,\theta}) + {}_{\sigma} CV_{v,\theta} (t_{v,\theta} - t_{a,\theta}) + RS_{a,\theta} + RL_{a,\theta} + RE_{a,\theta} \quad (3)$$

where

σ = air density
C = air specific heat
$V_{L,\theta}$ = volume flow rate of outdoor air infiltrating into room at time θ
$t_{o,\theta}$ = outdoor air temperature at time θ
$V_{v,\theta}$ = volume rate of flow of ventilation air at time θ
$t_{v,\theta}$ = ventilation air temperature at time θ
$RS_{a,\theta}$ = rate of solar heat coming through windows and convected into room air at time θ
$RL_{a,\theta}$ = rate of heat from lights convected into room air at time θ
$RE_{a,\theta}$ = rate of heat from equipment and occupants and convected into room air at time θ

Note that the space air temperature is allowed to float. By fixing the space air temperature, the cooling load need not be determined simultaneously.

This rigorous approach to calculating space cooling load is impractical without the speed at which some computations can be done by modern digital computers. Computer programs in use where instantaneous space cooling loads are calculated in this exact manner are primarily oriented to energy use calculations over extended periods (Mitalas and Stephenson 1967, Buchberg 1958, Walton 1982).

The transfer function concept is a simplification to the strict heat balance calculation procedure. In the transfer function concept, Mitalas and Stephenson (1967) used room thermal response factors. In their procedure, room surface temperatures and cooling load were first calculated by the rigorous method just described, for several typical constructions representing offices, schools, and dwellings of heavy, medium, and light construction. In these calculations, components such as solar heat gain, conduction heat gain, or heat gain from the lighting, equipment, and occupants were simulated by pulses of unit strength. The transfer functions were then calculated as numerical constants representing the cooling load corresponding to the input excitation pulses. Once these transfer functions were determined for typical constructions they were assumed independent of input pulses, thus permitting cooling loads to be determined without the more rigorous calculation. Instead, the calculation requires simple multiplication of the transfer functions by a time-series representation of heat gain and subsequent summation of these products, which can be carried out on a small computer. The same transfer function concept can be applied to calculating heat gain components themselves, as explained later.

Total Equivalent Temperature Differential Method

In the total equivalent temperature differential (TETD) method, the response factor technique was used with a number of representative wall and roof assemblies from which data were derived to calculate TETD values as functions of sol-air temperature and maintained room temperature. Various components of space heat gain are calculated using associated TETD values, and the results are added to internal heat gain elements to get an instantaneous total rate of space heat gain. This gain is converted to an instantaneous space cooling load by the time-averaging (TA) technique of averaging the radiant portions of the heat gain load components for the current hour with related values from an appropriate period of immediately preceding hours. This technique provides a rational means to deal quantitatively with the thermal storage phenomenon, but it is best solved by computer because of its complexity.

Transfer Function Method

Although similar in principle to TETD/TA, the transfer function method (TFM) (Mitalas 1972) applies a series of weighting factors, or conduction transfer function (CTF) coefficients to the various exterior opaque surfaces and to differences between sol-air temperature and inside space temperature to determine heat gain with appropriate reflection of thermal inertia of such surfaces. Solar heat gain through glass and various forms of internal heat gain are calculated directly for the load hour of interest. The TFM next applies a second series of weighting factors, or coefficients of room transfer functions (RTF), to heat gain and cooling load values from all load elements having radiant components, to account for the thermal storage effect in converting heat gain to cooling load. Both evaluation series consider data from several previous hours as well as the current hour. RTF coefficients relate specifically to the spatial geometry, configuration, mass, and other characteristics of the space so as to reflect weighted variations in thermal storage effect on a time basis rather than a straight-line average.

Transfer functions. These coefficients relate an output function at a given time to the value of one or more driving functions at a given time and at a set period immediately preceding. The CTF described in this chapter is no different from the thermal response factor used for calculating wall or roof heat conduction, while the RTF is the weighting factor for obtaining cooling load components (ASHRAE 1975). The bibliography lists reports of various experimental work that has validated the predictive accuracy of the TFM. While the TFM is scientifically appropriate and technically sound for a specific cooling load analysis, its computational complexity requires computer use for effective application in a commercial design environment.

CLTD/SCL/CLF Method

ASHRAE has sponsored research to compare the TETD/TA and TFM (Rudoy and Duran 1975). As part of this work, data obtained by using the TFM on a group of applications considered representative were then used to generate cooling load temperature differential (CLTD) data, for direct one-step calculation of cooling load from conduction heat gain through sunlit walls and roofs and conduction through glass exposures (see Bibliography). Cooling load factors (CLF) for similar one-step calculation of solar load through glass and for loads from internal sources were also developed. More recent research (McQuiston 1992) developed an improved factor for solar load through glass, the solar cooling load (SCL) factor, which allows additional influencing parameters to be considered for greater accuracy. CLTDs, SCLs, and CLFs all include the effect of (1) time lag in conductive heat gain through opaque exterior surfaces and (2) time delay by thermal storage in converting radiant heat gain to cooling load. This simplification allows cooling loads to be calculated manually; thus, when data are available and are appropriately used, the results are consistent with those from the TFM, thus making the method popular for instruction.

Application Experience

The CLTD and CLF tables published in previous editions of the Fundamentals volume and in the original *Cooling and Heating Load Calculation Manual* (ASHRAE 1979) are normalized data, based on applications of the original TFM data presented in the 1972 Fundamentals volume. Subsequent studies investigating the effects of 1981 to 1985 RTF data indicated results generally less conservative than those computed with the 1972 data. More recent research, however, suggests otherwise (McQuiston 1992), and the revised values for 1993, including the new SCLs, are currently considered more realistic for design load purposes.

CLTD Data. The originally developed CLTD data were so voluminous that they were first limited to 13 representative flat roof assemblies (with and without ceilings, for 26 total cases) and 7 wall groups (into which 41 different wall assemblies can be categorized). Twenty-four hourly CLTD values were tabulated for each of the 26 roof cases and each of the 7 wall groups, broken down for walls into 8 primary orientations. Adjustments were then required for specific north latitude and month of calculation. Reliability of adjustments was reasonably consistent during summer months but became much less realistic for early and late hours during traditionally noncooling load months.

Solar heat gain data. Solar heat gain through glass required similar data compression to present a corresponding range of conditions. Tables of maximum solar heat gain factors (SHGF) were listed for every 4° of north latitude between 0 and 64°, for each month and by 16 compass directions and horizontal. Cooling load factors (CLF), decimal multipliers for SHGF data, were tabulated for unshaded glass in spaces having carpeted or uncarpeted floors and for inside-shaded glass with any room construction. Unshaded CLFs were presented for each of 24 hours by 8 compass directions plus horizontal, further categorized by light, medium, or heavy room construction. Inside-shaded CLFs disregarded construction mass but included 16 orientations plus horizontal. The product of the selected CLTD and CLF values represented cooling load per unit area as a single process. CLF values published in the *Handbook* were derived for the period May through September as normally the hottest months for load calculation purposes. As with CLTDs, the reliability of CLF data deteriorated rapidly for applications during early and late hours of months considered "noncooling load" periods.

ASHRAE Research. For some space geometries and building constructions, the tabulated CLTD and CLF data published through 1989 were found also to be too restrictive or limited. The weighting factors used to generate these data, based on representative spaces in schools, offices, and dwellings at the time of the original research, did not reflect current design and construction practices. ASHRAE research investigated the sensitivity of the weighting factors to variations in space construction, size, exposure, and related conditions to update the tabular data. However, the investigators discovered that the range and amplitude of this sensitivity was much broader than previously thought, rendering even more impractical the generation of enough tabular material to cover the majority of normal applications. Accordingly, two significant changes in direction have occured:

1. The section describing the CLTD/CLF in the 1985 and 1989 editions of the Fundamentals volume recommended caution in application of this procedure for general practice, and this cautionary notice was also added as an insert to the *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992).
2. The system itself was modified for more specific tabulation of data, abandoning the maximum SHGF concept and incorporating solar cooling load (SCL) factors for estimating cooling load from glass.

The main thrust of recent ASHRAE research has been to update the *Cooling and Heating Load Calculation Manual.* Information from earlier research was used to revise the original factors by incorporating additional parameters, including separating solar load through glass from the CLF category and creating more appropriate SCL factors for that component. Still faced with too much tabular data, information was tabulated only for limited use and representative examples, but it was accompanied by instructions for customizing similar data for specific application; a microcomputer database was also provided to facilitate such calculations. Certain limitations resulting from normalization of data remain, for which anticipated error ranges are listed to aid in evaluating results. The section in this chapter describing the CLTD/SCL/CLF method has incorporated this latest research, but it does not provide the microcomputer program.

TETD/TA Method. Prior to introduction of the CLTD/CLF, most users had turned to computer-based versions of the time-averaging technique, proven successful and practical in ten years of heavy use. Most users, however, recognized the subjectivity of determining the relative percentages of radiant heat in the various heat gain components and selecting the number of hours over which to average such loads—both of which must rely on the individual experience of the user rather than on research or support in the scientific literature. Harris and McQuiston (1988) developed decrement factors and time lag values. In this chapter, these factors have been keyed to typical walls and roofs. All other tabular data pertaining to this method has been deleted, so that since 1989, information has been confined to basic algorithms intended for continued computer applications.

Primary emphasis of future research. Because of the increasing availability and power of microcomputers, emphasis has refocused on the more specific and flexible transfer function method as the fundamental computational technique. Future research will concentrate on refining the weighting factors and broadening the range of circumstances to which the TFM can be applied.

Alternative procedures. The CLTD/SCL/CLF and TETD/TA procedures, tables, and related data will continue to be appropriate and dependable when applied within the limitations identified. Users will likely incorporate newer relationships developed for TFM usage in the development of specific CLTD/SCL/CLF or TETD/TA tabular data, customized for their specialized projects.

INITIAL DESIGN CONSIDERATIONS

To calculate a space cooling load, detailed building design information and weather data at selected design conditions are required. Generally, the following steps should be followed:

Data Assembly

1. **Building characteristics.** Obtain characteristics of the building. Building materials, component size, external surface colors and shape are usually determined from building plans and specifications.
2. **Configuration.** Determine building location, orientation and external shading from building plans and specifications. Shading from adjacent buildings can be determined by a site plan or by visiting the proposed site, but should be carefully evaluated as to its probable permanence before it is included in the calculation. The possibility of abnormally high ground-reflected solar radiation (*i.e.*, from adjacent water, sand, or parking lots), or solar load from adjacent reflective buildings should not be overlooked.
3. **Outdoor design conditions.** Obtain appropriate weather data and select outdoor design conditions. Weather data can be obtained from local weather stations or from the National Climatic Center, Asheville, NC 28801. For outdoor design

conditions for a large number of weather stations, see Chapter 24. Note, however, that the scheduled values for 5%, 2-1/2%, or even 1% design dry-bulb and mean coincident wet-bulb temperatures can vary considerably from data traditionally used in various areas. Use appropriate judgment to ensure that results are consistent with expectations. Also, consider prevailing wind velocity and the relationship of a project site to the selected weather station.

4. **Indoor design conditions**. Select indoor design conditions, such as indoor dry-bulb temperature, indoor wet-bulb temperature, and ventilation rate. Include permissible variations and control limits.
5. **Operating schedules**. Obtain a proposed schedule of lighting, occupants, internal equipment, appliances, and processes that contribute to the internal thermal load. Determine the probability that the cooling equipment will be operated continuously or shut off during unoccupied periods (*e.g.*, nights and/or weekends).
6. **Date and time**. Select the time of day and month to do the cooling load calculation. Frequently, several different times of day and several different months must be analyzed to determine the peak load time. The particular day and month are often dictated by peak solar conditions, as tabulated in Tables 3 through 11 in Chapter 27. For southern exposures in north latitudes above 32° having large fenestration areas, the peak space cooling load usually occurs in December or January. To calculate a space cooling load under these conditions, the warmest temperature for the winter months must be known. These data can be found in the National Climatic Center's Climatic Atlas of the United States.

Use of data. Once the data is assembled, calculate the space cooling load at design conditions, as outlined in the following sections of this chapter.

Additional Considerations

The proper design and sizing of all-air or air-and-water central air-conditioning systems require more than calculation of the cooling load in the space to be conditioned. The type of air-conditioning system, fan energy, fan location, duct heat loss and gain, duct leakage, heat extraction lighting systems, and type of return air system all affect system load and component sizing. Adequate system design and component sizing require that system performance be analyzed as a series of psychrometric processes. Chapter 3 of the 1992 ASHRAE *Handbook—Systems and Equipment* describes some elements of this technique in detail, while others are delineated in this chapter.

HEAT GAIN CALCULATION CONCEPTS

Heat Gain through Fenestration Areas

The primary weather-related variable influencing the cooling load for a building is solar radiation. The effect of solar radiation is more pronounced and immediate in its impact on exposed nonopaque surfaces. The calculation of solar heat gain and conductive heat transfer through various glazing materials and associated mounting frames, with or without interior and/or exterior shading devices, is discussed in Chapter 27. This chapter covers the application of such data to the overall heat gain evaluation and the conversion of the calculated heat gain into a composite cooling load for the conditioned space.

Heat Gain through Exterior Surfaces

Heat gain through exterior opaque surfaces is derived from the same elements of solar radiation and thermal gradient as that for fenestration areas. It differs primarily as a function of the mass and nature of the wall or roof construction, since those elements affect the rate of conductive heat transfer through the composite assembly to the interior surface.

Sol-Air Temperature

Sol-air temperature is the temperature of the outdoor air that, in the absence of all radiation changes, gives the same rate of heat entry into the surface as would the combination of incident solar radiation, radiant energy exchange with the sky and other outdoor surroundings, and convective heat exchange with the outdoor air.

Heat flux into exterior sunlit surfaces. The heat balance at a sunlit surface gives the heat flux into the surface q/A as

$$q/A = \alpha I_t + h_o(t_o - t_s) - \epsilon \Delta R \tag{4}$$

where

α = absorptance of surface for solar radiation
I_t = total solar radiation incident on surface, Btu/(h·ft²)
h_o = coefficient of heat transfer by long-wave radiation and convection at outer surface, Btu/(h·ft²·°F)
t_o = outdoor air temperature, °F
t_s = surface temperature, °F
ϵ = hemispherical emittance of surface
R = difference between long-wave radiation incident on surface from sky and surroundings and radiation emitted by blackbody at outdoor air temperature, Btu/(h·ft²)

Assuming the rate of heat transfer can be expressed in terms of the sol-air temperature t_e

$$q/A = h_o(t_e - t_s) \tag{5}$$

and from Equations (4) and (5)

$$t_e = t_o + \alpha I_t/h_o - \epsilon \Delta R/h_o \tag{6}$$

Horizontal surfaces. For horizontal surfaces that receive long-wave radiation from the sky only, an appropriate value of ΔR is about 20 Btu/(h·ft²), so that if $\epsilon = 1$ and $h = 3.0$ Btu/(h·ft²·°F), the long-wave correction term is about −7 °F (Bliss 1961).

Vertical surfaces. Because vertical surfaces receive long-wave radiation from the ground and surrounding buildings as well as from the sky, accurate ΔR values are difficult to determine. When solar radiation intensity is high, surfaces of terrestrial objects usually have a higher temperature than the outdoor air; thus, their long-wave radiation compensates to some extent for the sky's low emittance. Therefore, it is common practice to assume $\Delta R = 0$ for vertical surfaces.

Tabulated temperature values. The sol-air temperatures in Table 1 have been calculated based on $\Delta R/h_o$ being −7 °F for horizontal surfaces and 0 °F for vertical surfaces; total solar intensity values used for the calculations were the same as those used to evaluate the solar heat gain factors (SHGF) for July 21 at 40 °N latitude (Chapter 27). These values of I_t incorporate diffuse radiation from a clear sky and ground reflection, but make no allowance for reflection from adjacent walls.

Surface colors. Sol-air temperature values are given for two values of the parameter α/h_o (Table 1); the value of 0.15 is appropriate for a light-colored surface, while 0.30 represents the usual maximum value for this parameter (*i.e.*, for a dark-colored surface, or any surface for which the permanent lightness can not reliably be anticipated).

Air temperature cycle. The air temperature cycle used to calculate the sol-air temperatures is given in Column 2, Table 1. Sol-air temperatures can be adjusted to any other air temperature cycle simply by adding or subtracting the difference between the desired air temperature and the air temperature value given in Column 2.

Table 1 Sol-Air Temperatures t_e for July 21, 40 °N Latitude

Note: Sol-air temperatures are calculated based on $\epsilon\delta/h_o$ = −7 °F for horizontal surfaces and 0 °F for vertical surfaces.

Adjustments. Sol-air temperature cycles can be estimated for other dates and latitudes by using the data in Tables 12 through 18, Chapter 27. For any of the times, dates, and wall orientations listed in those tables, the value of I_t is approximately 1.15 × SHGF. However, the 1.15 factor is approximate and only accounts for the solar energy excluded by a single sheet of ordinary window glass. For surfaces with other orientations or slope angles of other than 0°, and for more accurate estimates at incident angles above 50° (particularly critical for southern exposures), the solar intensity can be found by the method outlined in Chapter 27.

Average sol-air temperature. The average daily sol-air temperature t_{ea} can be calculated for any of the situations covered by Tables 12 through 18 of Chapter 27:

$$t_{ea} = t_{oa} + \alpha/[h_o(I_{DT}/24)] - (\epsilon\Delta R/h_o) \quad (7)$$

where I_{DT} is the sum of two appropriate half-day totals of solar heat gain in Btu/(h·ft²). For example, the average sol-air temperature for a wall facing southeast at 40 °N latitude on August 21 would be

$$t_{ea} = t_{oa} + \alpha/h_o[1.15(956 + 205)/24]$$

The daily solar heat gain of double-strength sheet glass is 956 + 205 Btu/(h·ft²) in a southeast facade at this latitude and date (Table 16, Chapter 27); and $\epsilon\Delta R/h_o$ is assumed to be zero for this vertical surface.

Hourly air temperatures. The hourly air temperatures in Column 2, Table 1 are for a location with a design temperature of 95 °F and a range of 21 °F. To compute corresponding temperatures for other locations, select a suitable design temperature from Column 6, Table 1 of Chapter 24 and note the outdoor daily range (Column 7). For each hour, take the percentage of the daily range indicated in Table 2 of this chapter and subtract from the design temperature.

Table 2 Percentage of Daily Range

Time, h	%	Time, h	%	Time, h	%
1	87	9	71	17	10
2	92	10	56	18	21
3	96	11	39	19	34
4	99	12	23	20	47
5	100	13	11	21	58
6	98	14	3	22	68
7	93	15	0	23	76
8	84	16	3	24	82

Example 1. Air temperature calculation. Calculate the summer dry-bulb temperature at 1200 h for Carson City, Nevada.

Solution: From Table 1, Chapter 24, the daily range is 42 °F and the 1% design dry-bulb temperature is 93 °F. From Table 2, the percentage of the daily range at 1200 hours is 23%. Thus, the dry-bulb temperature at 1200 *h* = Design dry-bulb − (Daily range × Percentage) = 93.0 − [42(23/100)] = 83.3 °F.

Data limitations. The summer design temperatures in Table 1, Chapter 24, are based on the 4-month period, June through September. (Canadian data are based on July only.) The outdoor daily range is the difference between the average daily maximum and average daily minimum temperatures during the warmest month. More reliable results could be obtained by determining or estimating the shape of the temperature curve for typical hot days at the building site and considering each month separately. Peak cooling load is often determined by solar heat gain through fenestration; this peak may occur in winter months and/or at a time of day when outside air temperature is not at its peak.

Heat Gain through Fenestration

The sections that include Equations (30) through (41) in Chapter 27 describe one method used to calculate space cooling load resulting from heat transfer through fenestration. The solar heat gain profiles listed in Chapter 27 are for fenestration areas with

no external shading. The equations for calculating shade angles (Chapter 27) can be used to determine the shape and area of moving shadow falling across a given window from external shading elements during the course of a design day. Thus, a subprofile of heat gain for that window can be created by separating its sunlit and shaded areas for each hour; modifying multipliers for inside shading devices can also be included.

Exterior shading. Nonuniform exterior shading, caused by roof overhangs, side fins, or building projections, require separate hourly calculations for the externally shaded and unshaded areas of the window in question, with the SC still used to account for any internal shading devices. The areas, shaded and unshaded, depend on the location of the shadow line on a surface in the plane of the glass. Sun (1968) developed fundamental algorithms for analysis of shade patterns. The *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992) provides graphical data to facilitate shadow line calculation, and the north exposure SHGF may be taken for shaded glass (with some loss of accuracy at latitudes less than 24° north).

An alternate, more accurate, method suggested by Todorovic and Curcija (1984) first calculates cooling loads as if the external shading were absent, then adjusts (reduces) the result to account for the shading effect. This correction applies a "negative cooling load factor," calculated in much the same way as a conventional cooling load but using the time-varying area of the shaded portion of the glass as the heat gain element. Todorovic (1987) describes the solution of the moving shade line problem in the context of consequent cooling load.

Temperature considerations. To estimate the conduction flow of heat through a fenestration at any time, applicable values of the outdoor and indoor dry-bulb temperatures must be used. Chapter 24 gives design values of summer outdoor dry-bulb temperatures for many locations. These are generally mid-afternoon temperatures; for other times, local weather stations or NOAA can supply temperature data. Winter design temperatures should not be used in Equation (15), since such data are for heating design rather than coincident conduction heat gain with sunlit glass during the heating season.

Heat Gain through Interior Surfaces

Whenever a conditioned space is adjacent to a space with a different temperature, transfer of heat through the separating physical section must be considered. The heat transfer rate is given by

$$q = UA(t_b - t_i) \tag{8}$$

where

q = heat transfer rate, Btu/h
U = coefficient of overall heat transfer between adjacent and conditioned space, Btu/(h·ft²·°F)
A = area of separating section concerned, ft²
t_b = average air temperature in adjacent space, °F
t_i = air temperature in conditioned space, °F

Values of U can be obtained from Chapter 22. Temperature t_b may range widely from that in the conditioned space. The temperature in a kitchen or boiler room, for example, may be as much as 15 to 50°F above the outdoor air temperature. Actual temperatures in adjoining spaces should be measured when possible. Where nothing is known, except that the adjacent space is of conventional construction, contains no heat sources, and itself receives no significant solar heat gain, $t_b - t_i$ may be considered the difference between the outdoor air and conditioned space design dry-bulb temperatures minus 5°F. In some cases, the air temperature in the adjacent space will correspond to the outdoor air temperature or higher.

Floors. For floors directly in contact with the ground, or over an underground basement that is neither ventilated nor conditioned, heat transfer may be neglected for cooling load estimates.

HEAT SOURCES IN CONDITIONED SPACES

People

Table 3 gives representative rates at which heat and moisture are given off by human beings in different states of activity. Often these sensible and latent heat gains constitute a large fraction of the total load. For short occupancy, the extra heat and moisture brought in by people may be significant. For further details, see Chapter 8.

While Chapter 8 should be referred to for detailed information, Table 3 summarizes practical data representing conditions commonly encountered.

The conversion of sensible heat gain from people to space cooling load is affected by the thermal storage characteristics of that space and is thus subject to application of appropriate room transfer functions (RTF). Latent heat gains are considered instantaneous.

Lighting

Since lighting is often the major space load component, an accurate estimate of the space heat gain it imposes is needed. Calculation of this load component is not straightforward; the rate of heat gain at any given moment can be quite different from the heat equivalent of power supplied instantaneously to those lights.

Only part of the energy from lights is in the form of convective heat, which is picked up instantaneously by the air-conditioning apparatus. The remaining portion is in the form of radiation, which affects the conditioned space only after having been absorbed and rereleased by walls, floors, furniture, etc. This absorbed energy contributes to space cooling load only after a time lag, with some part of such energy still present and reradiating after the lights have been switched off (Figure 2).

There is always significant delay between the time of switching lights on and a point of equilibrium where reradiated light energy equals that being instantaneously stored. Time lag effect must be considered when calculating cooling load, since load felt by the space can be considerably lower than the instantaneous heat gain being generated, and peak load for the space may be affected significantly.

Instantaneous heat gain from lighting. The primary source of heat from lighting comes from light-emitting elements, or lamps, although significant additional heat may be generated from associated appurtenances in the light fixtures that house such

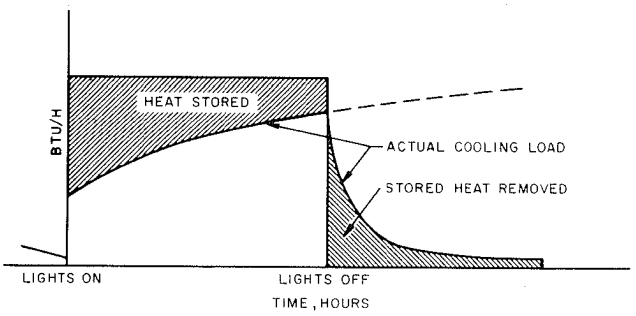

Fig. 2 Thermal Storage Effect in Cooling Load from Lights

lamps. Generally, the instantaneous rate of heat gain from electric lighting may be calculated from

$$q_{el} = 3.41\ W F_{ul} F_{sa} \quad (9)$$

where

q_{el} = heat gain, Btu/h
W = total light wattage
F_{ul} = lighting use factor
F_{sa} = lighting special allowance factor

The *total light wattage* is obtained from the ratings of all lamps installed, both for general illumination and for display use.

The *use factor* is the ratio of the wattage in use, for the conditions under which the load estimate is being made, to the total installed wattage. For commercial applications such as stores, the use factor would generally be unity.

The *special allowance factor* is for fluorescent fixtures and/or fixtures that are either ventilated or installed so that only part of their heat goes to the conditioned space. For fluorescent fixtures, the special allowance factor accounts primarily for ballast losses, and can be as high as 2.19 for 32-W single lamp high-output fixtures on 277 V circuits. Rapid-start, 40-W lamp fixtures have special allowance factors that vary from a low of 1.18 for two lamps at 277 V to a high of 1.30 for one lamp at 118 V, with a recommended value of 1.20 for general applications. Industrial fixtures other than fluorescent, such as sodium lamps, may have special allowance factors varying from 1.04 to 1.37, depending on the manufacturer, and should be dealt with individually.

For *ventilated* or *recessed* fixtures, manufacturers' or other data must be sought to establish the fraction of the total wattage that may be expected to enter the conditioned space directly (and subject to time lag effect), versus that which must be picked up by return air or in some other appropriate manner.

Light heat components. Cooling load caused by lights recessed into ceiling cavities is made up of two components: one part comes from the light heat directly contributing to the space heat gain, and the other is the light heat released into the above-ceiling cavity, which (if used as a return air plenum) is mostly picked up by the return air that passes over or through the light fixtures. In such a ceiling return air plenum, this second part of the load (sometimes referred to as heat-to-return) never enters the conditioned space. It does, however, add to the overall load and significantly influences the load calculation.

Even though the total cooling load imposed on the cooling coil from these two components remains the same, the larger the fraction of heat output picked up by the return air, the more the space cooling load is reduced. The minimum required airflow rate for the conditioned space is decreased as the space cooling load becomes less. Supply fan horsepower reduces accordingly, which ultimately results in reduced energy consumption for the system, and, possibly reduced equipment size as well.

For ordinary design load estimation, the heat gain for each component may simply be calculated as a fraction of the total lighting load by using judgment to estimate heat-to-space and heat-to-return percentages (Mitalas and Kimura 1971).

Return air light fixtures. Two generic types of return air light fixture are available—those that allow and those that do not allow return air to flow through the lamp chamber. The first type is sometimes called a heat-of-light fixture. The percentage of light heat released through the plenum side of various ventilated fixtures can be obtained from lighting fixture manufacturers. For representative data, see Nevens *et al.* (1971). Even unventilated fixtures lose some heat to plenum spaces; however, most of the heat ultimately enters the conditioned space from a dead-air plenum or is picked up by return air via ceiling return air openings. The percentage of heat to return air ranges from 40 to 60% for heat-to-return ventilated fixtures or 15 to 25% for unventilated fixtures.

Plenum temperatures. As heat from lighting is picked up by the return air, the temperature differential between the ceiling space and the conditioned space causes part of that heat to flow from the ceiling back to the conditioned space. Return air from the conditioned space can be ducted to capture light heat without passing through a ceiling plenum as such, or the ceiling space can be used as a return air plenum, causing the distribution of light heat to be handled in distinctly different ways. Most plenum temperatures do not rise more than 1 to 3 °F above space temperature, thus generating only a relatively small thermal gradient for heat transfer through plenum surfaces but a relatively large percentage reduction in space cooling load. (Many engineers believe that a

Notes:
1. Tabulated values are based on 75 °F room dry-bulb temperature. For 80 °F room dry bulb, the total heat remains the same, but the sensible heat values should be decreased by approximately 20%, and the latent heat values increased accordingly.
2. Also refer to Table 4, Chapter 8, for additional rates of metabolic heat generation.
3. All values are rounded to nearest 5 Btu/h.

[a] Adjusted heat gain is based on normal percentage of men, women, and children for the application listed, with the postulate that the gain from an adult female is 85% of that for an adult male, and that the gain from a child is 75% of that for an adult male.

[b] Values approximated from data in Table 6, Chapter 8, where V is air velocity with limits shown in that table.

[c] Adjusted heat gain includes 60 Btu/h for food per individual (30 Btu/h sensible and 30 Btu/h latent).

[d] Figure one person per alley actually bowling, and all others as sitting (400 Btu/h) or standing or walking slowly (550 Btu/h).

major reason for plenum temperatures not becoming more elevated is due to leakage into the plenum from supply air duct work normally concealed there, but consideration of this elusive factor is beyond the scope of this chapter.)

Energy balance. Where the ceiling space is used as a return air plenum, an energy balance requires that the heat picked up from the lights into the return air (1) becomes a part of the cooling load to the return air (represented by a temperature rise of the return air as it passes through the ceiling space), (2) is partially transferred back into the conditioned space through the ceiling material below, and/or (3) may be partially "lost" (from the space) through the floor surfaces above the plenum. In a multistory building, the conditioned space frequently gains heat through its floor from a similar plenum below, offsetting the loss just mentioned. The radiant component of heat leaving the ceiling or floor surface of a plenum is normally so small that all such heat transfer is considered convective for calculation purposes.

Figure 3 shows a schematic diagram of a typical return air plenum. Equations (10) through (14), using the sign convention as shown in Figure 3, represent the heat balance of a return air plenum design for a typical interior room in a multifloor building, as

$$q_1 = U_c A_c (t_p - t_r) \tag{10}$$

$$q_2 = U_f A_f (t_p - t_{fa}) \tag{11}$$

$$q_3 = 1.1\, Q (t_p - t_r) \tag{12}$$

$$q_{lp} - q_2 - q_1 - q_3 = 0 \tag{13}$$

$$Q = (q_r + q_1)/[1.1\,(t_r - t_s)] \tag{14}$$

where

q_1 = heat gain to space from plenum through ceiling, Btu/h
q_2 = heat loss from plenum through floor above, Btu/h
q_3 = heat gain "pickup" by return air, Btu/h
Q = return airflow, cfm
q_{lp} = light heat gain to plenum via return air, Btu/h
q_{lr} = light heat gain to space, Btu/h
q_f = heat gain from plenum below, through floor, Btu/h
q_w = heat gain from exterior wall, Btu/h
q_r = space cooling load, Btu/h, including appropriate treatment of q_{lr}, q_f, and/or q_w
t_p = plenum temperature, °F
t_r = space temperature, °F
t_{fa} = space temperature of floor above, °F
t_s = supply air temperature, °F

By substituting Equations (10), (11), (12), and (14) into heat balance equation (13), t_p can be found as the resultant return air temperature or plenum temperature, by means of a quadratic equation derived from such relationships. The results, although rigorous and best solved by computer, are important in determining the cooling load, which affects equipment size selection, future energy consumption, and other factors.

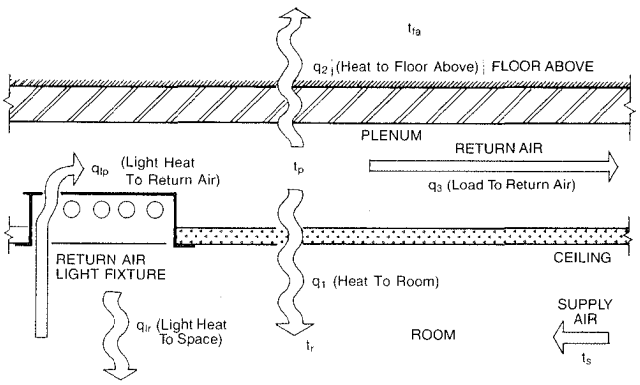

Fig. 3 Heat Balance of Typical Ceiling Return Plenum

Equations (10) through (14) are simplified to illustrate the heat balance relationship. Heat gain into a return air plenum is not limited to the heat of lights alone. Exterior walls directly exposed to the ceiling space will transfer heat directly to or from the return air. For single-story buildings or the top floor of a multistory building, the roof heat gain or loss enters or leaves the ceiling plenum rather than entering or leaving the conditioned space directly. The supply air quantity calculated by Equation (14) is for the conditioned space under consideration only, and is assumed equal to the return air quantity.

The amount of airflow through a return plenum above a conditioned space may not be limited to that supplied into the space under consideration; it will, however, have no noticeable effect on plenum temperature if the surplus comes from an adjacent plenum operating under similar conditions. Where special conditions exist, heat balance Equations (10) through (14) must be modified appropriately. Finally, even though the building's thermal storage has some effect, the amount of heat entering the return air is small and may be considered as convective for calculation purposes.

Power

Instantaneous heat gain from equipment operated by electric motors within a conditioned space is calculated as

$$q_{em} = 2545\,(P/E_M)(F_{UM})(F_{LM}) \tag{15}$$

where

q_{em} = heat equivalent of equipment operation, Btu/h
P = motor power rating, horsepower
E_M = motor efficiency, as decimal fraction < 1.0
F_{UM} = motor use factor, 1.0 or decimal fraction < 1.0
F_{LM} = motor load factor, 1.0 or decimal fraction < 1.0

The motor use factor may be applied when motor use is known to be intermittent with significant nonuse during all hours of operation (*e.g.*, overhead door operator). For conventional applications, its value would be 1.0.

The motor load factor is the fraction of the rated load being delivered under the conditions of the cooling load estimate. In Equation (15), it is assumed that both the motor and the driven equipment are within the conditioned space. If the motor is outside the space or airstream

$$q_{em} = 2545\,P(F_{UM})(F_{LM}) \tag{16}$$

When the motor is inside the conditioned space or airstream but the driven machine is outside

$$q_{em} = 2545\,P[(1.0 - E_M)/E_M(F_{UM})(F_{LM}) \tag{17}$$

Equation (17) also applies to a fan or pump in the conditioned space that exhausts air or pumps fluid outside that space.

Average efficiencies, and related data representative of typical electric motors, generally derived from the lower efficiencies reported by several manufacturers of open, drip-proof motors, are given in Tables 4 and 5. These reports indicate that TEFC (totally enclosed fan-cooled) are slightly more efficient. For speeds lower or higher than those listed, efficiencies may be 1 to 3% lower or higher, depending on the manufacturer. Should actual voltages at motors be appreciably higher or lower than rated nameplate voltage, efficiencies in either case will be lower. If electric motor load is an appreciable portion of cooling load, the motor efficiency should be obtained from the manufacturer. Also, depending on

Table 5 Typical Overload Limits with Standard Motors

Horsepower	0.05-0.25	0.16-0.33	0.67-0.75	1 and up
AC open	1.4	1.35	1.25	1.15
AC TEFC[a] and DC	—	1.0	1.0	1.0

Note: Some shaded pole, capacitor start, and special purpose motors have a service factor varying from 1.0 up to 1.75.
[a]Some totally enclosed fan-cooled (TEFC) motors have a service factor above 1.0.

design, the maximum efficiency might occur anywhere between 75 to 110% of full load; if underloaded or overloaded, the efficiency could vary from the manufacturer's listing.

Overloading or underloading. Heat output of a motor is generally proportional to the motor load, within the overload limits. Because of typically high no-load motor current, fixed losses, and other reasons, FLM is generally assumed to be unity, and no adjustment should be made for underloading or overloading unless the situation is fixed, can be accurately established, and the reduced load efficiency data can be obtained from the motor manufacturer.

Radiation and convection. Unless the manufacturer's technical literature indicates otherwise, the heat gain normally should be equally divided between radiant and convective components for the subsequent cooling load calculations.

Appliances

In a cooling load estimate, heat gain from all appliances—electrical, gas, or steam—should be taken into account. Because of the variety of appliances, applications, usage schedules, and installations, estimates are very subjective.

Food preparation equipment. This equipment includes the most common types of heat-producing appliances found in the conditioned areas. Marn (1962) found that appliance surfaces contribute most of the heat to commercial kitchens and that when installed under an effective hood, the cooling load is independent of the fuel or energy employed for similar equipment performing the same operations. Marn's tests also indicated that the heat is primarily radiant energy from the appliance surfaces and cooking utensils and that convected and latent heat are negligible.

To establish a heat gain value, actual nameplate energy input ratings should be used with appropriate usage factors, efficiencies, or other judgmental modifiers. Where specific rating data are not available (nameplate missing, equipment not yet purchased, etc.) or as an alternative approach, recommended heat gains tabulated in this chapter for a wide variety of commonly encountered equipment items may be used. In estimating the appliance load, probabilities of simultaneous use and operation for different appliances located in the same space must be considered.

Radiation contributes up to 32% of the maximum hourly heat input to hooded appliances (Talbert *et al.* 1973), suggesting a conservative estimate of heat released into the kitchen, or radiation factor $F_{RA} = 0.32$. Marn (1962) found that radiant heat temperature rises can be substantially reduced by shielding the fronts of cooking appliances. These reductions amounted to 59% with asbestos paper, 61% with glass panels, and 78% using polished aluminum shielding. A floor-slot air curtain in front of the appliances reduced the radiant temperature rise by 15%.

Heat gain from meals. For each meal served the heat transferred to the dining space is approximately 50 Btu/h, of which 75% is sensible and 25% latent.

Heat gain for electric and steam appliances. The maximum hourly input can be estimated as 50% of the total nameplate or catalog input q_i ratings because of diversity of appliance use and the effect of thermostatic controls, giving a usage factor $F_{UA} = 0.50$. Therefore, the maximum hourly heat gain q_m for generic types of electric and steam appliances installed under a hood can be estimated from the following equations

$$q_{sensible} = q_{is}(F_{UA})(F_{RA}) \tag{18}$$

or, for electric or steam,

$$q_{sensible} = 0.16\ q_{is} \tag{19}$$

Heat gain from gas-fired appliances. Direct fuel-fired cooking appliances require more heat input than electric or steam equipment of the same type and size. In the case of gas fuel, the American Gas Association (1948, 1950) established an overall figure of approximately 60% more. Marn (1962) confirmed that where the appliances are installed under an effective hood, only radiant heat adds to the cooling load; convected and latent heat from the cooking process and combustion products are exhausted and do not enter the kitchen. It is therefore necessary to adjust Equation (18) for use with fuel-fired appliances, to compensate for the 60% higher input ratings, since the appliance surface temperatures are the same, and the extra heat input and combustion products are exhausted to outdoors. This correction is made by the introduction of a flue loss factor (FFL) of 1.60 as follows

$$q_{sensible} = [q_{is}(F_{UA})(F_{RA})]/F_{FL} \tag{20}$$

or, for fuel-fired appliances,

$$q_{sensible} = 0.10\ q_{is} \tag{21}$$

Latent heat gain from appliances. Latent heat gain from any kind of appliance is instantaneous, taken as the latent rating for the particular item, conditioned by the usage factor, or

$$q_{latent} = q_{il}(F_{UA}) \quad (22)$$

Table 6 lists factors for seven typical electrical, steam, or gas appliances; Table 7 lists the relative efficiencies of various types of commercial cooking equipment and gives a representative efficiency ratio for each (Alereza and Breen 1984).

Unhooded equipment. For all cooking appliances not installed under an exhaust hood or directly vent-connected and located in the conditioned area, the heat gain may be estimated as 50% (usage factor = 0.50) of the rated hourly input, regardless of the type of energy or fuel used. On average, 34% of the heat may be assumed to be latent and the remaining 66% sensible heat.

Recommended heat gain values. As an alternative procedure, Table 8 lists recommended rates of heat gain from typical commercial cooking appliances (Alereza and Breen 1984). The data in the "with hood" columns assume installation under a properly designed exhaust hood connected to a mechanical fan exhaust system.

Hospital and laboratory equipment. Hospital and laboratory equipment items are major sources of heat gain in conditioned spaces. Care must be taken in evaluating the probability and duration of simultaneous usage when many components are concentrated in one area, such as laboratory, operating room, etc. Commonly, heat gain from equipment in a laboratory ranges from 15 to 70 Btu/(h · ft²) or, in laboratories with outdoor exposure, as much as four times the heat gain from all other sources combined.

Table 6 Heat Gain Factors of Typical Appliances under Hoods

Appliance	Usage Factor F_{UA}	Radiation Factor F_{RA}	Load Factor $F_L = F_{UA}F_{RA}$ Elec. or Steam	Load Factor $F_L = F_{UA}F_{RA}/F_{FL}$ Gas

Hot plate	48	23

Table 3 in Chapter 30 of the 1991 ASHRAE *Handbook—Applications* lists heat gain values for various hospital and laboratory equipment.

Office appliances. Electric typewriters, calculators, checkwriters, teletype units, posting machines, etc., can generate 3 to 4 Btu/(h · ft²) for general offices or 6 to 7 Btu/(h · ft²) for purchasing and accounting departments. However, in offices having computer display terminals at most desks, heat gains range up to 15 Btu/(h · ft²) (Table 9).

Computer rooms housing mainframe or minicomputer equipment must be considered individually. Computer manufacturers have data pertaining to various individual components. Additional insight should be sought from data processing managers as to schedules, near-term future planning, etc. Heat gain rates from digital computer equipment range from 75 to 175 Btu/(h · ft²). While the trend in hardware development is toward less heat release on a component basis, the associated miniaturization tends to offset such unitary reduction by a higher concentration of equipment. Chapter 33 of the 1991 ASHRAE *Handbook—Applications* gives further information on the air conditioning of data processing areas.

INFILTRATION AND VENTILATION HEAT GAIN

Ventilation

Outdoor air must be introduced to ventilate conditioned spaces. Chapter 23 suggests minimum outdoor air requirements for representative applications, but the minimum levels are not necessarily adequate for all psychological attitudes and physiological responses. Where maximum economy in space and load is essential, as in submarines or other restricted spaces, as little as 1 cfm of outdoor air per person can be sufficient, provided that recirculated air is adequately decontaminated (Consolazio and Pecora 1947).

Local codes and ordinances frequently specify ventilation requirements for public places and for industrial installations. For example, minimum requirements for safe practice in hospital operating rooms are given in NFPA *Standard* 99 (1990). Although 100% outdoor air is sometimes used in operating rooms, this standard does not require it, and limiting the outdoor air to 6 to 8 changes per hour is finding increasing acceptance.

ASHRAE *Standard* 62 (1989) recommends minimum ventilation rates for most common applications. For general applications, such as offices, 20 cfm per person is suggested.

Ventilation air is normally introduced at the air-conditioning apparatus rather than directly into the conditioned space, and thus becomes a cooling coil load component instead of a space load component. Calculations for estimating this heat gain are discussed later.

Reducing heat gain from outdoor air by using filtered recirculated air in combination with outdoor air should be considered. Recirculated air can also be treated to control odor (see Chapter 12 in this volume and Chapter 50 in the 1991 ASHRAE *Handbook—Applications*). To provide for physiological needs, the outdoor air quantity should never be less than 4 cfm per person.

Infiltration

The principles of estimating infiltration in buildings, with emphasis on the heating season, are discussed in Chapter 23. For the cooling season, infiltration calculations are usually limited to doors and windows. However, in multistory commercial buildings, outdoor air may infiltrate at the top of the building and exfiltrate at the bottom.

Air leakage through doors can be estimated using the information in Chapter 23. Tables 4 and 6, Chapter 23, adjusted for the

Table 8 Recommended Rate of Heat Gain from Restaurant Equipment Located in Air-Conditioned Area

Water cooler	32 qt/h	2390	—	5970

[a]Input is not proportional to capacity.

average wind velocity in the locality, may be used to compute infiltration for windows. In calculating window infiltration for an entire structure, the total window area on all sides of the building is not involved, since wind does not act on all sides simultaneously. In any case, infiltration from all windows in any two adjacent wall exposures should be included. A knowledge of the prevailing wind direction and velocity is helpful in selecting exposures.

When economically feasible, sufficient outdoor air should be introduced as ventilation air through the air-conditioning equipment to maintain a constant outward escape of air, and thus eliminate the infiltration portion of the gain. The pressure maintained must overcome wind pressure through cracks and door openings. When the quantity of outside air introduced through the cooling equipment is not sufficient to maintain the required pressure to eliminate infiltration, the entire infiltration load should be included in the space heat gain calculations.

Standard Air Defined

Since the specific volume of air varies appreciably, calculations will be more accurate when made on the basis of air mass instead of volume. However, volume values are often required for selection of coils, fans, ducts, etc., in which cases volume values based on measurement at standard conditions may be used for accurate results. One standard value is 0.075 lb of dry air/ft^3 (13.33 ft^3/lb of dry air). This density corresponds to about 60 °F at saturation, and 69 °F dry air (at 14.7 psia). Because air usually passes through the coils, fans, ducts, etc. at a density close to standard, the accuracy desired normally requires no correction. When airflow is to be measured at a particular condition or point, such as at a coil entrance or exit, the corresponding specific volume can be taken from the psychrometric chart and the standard volume multiplied by the ratio of the actual specific volume divided by 13.33.

Example 2. Standard air calculations. Assume that the outdoor air at standard conditions is 1000 cfm. What is the flow rate when the outdoor air is at 95 °F dry-bulb and 75 °F wet-bulb (14.3 ft^3/lb)? The measured rate at that condition should be 1000(14.3/13.33) = 1070 cfm.

Solution: Air-conditioning design often requires calculation of:

1. Total heat

Total heat gain, in Btu/h, corresponding to the change of a given standard flow rate Q_s through an enthalpy difference Δh

$$\text{Total heat change} = 60 \times 0.075\, Q_s \Delta h = 4.5\, Q_s \Delta h \quad (23)$$

where 60 = min/h and 0.075 = lb of dry air/ft^3.

2. Sensible heat

Sensible heat gain corresponding to the change of dry-bulb temperature Δt for given airflow (standard conditions) Q_s, or sensible heat change q_s, in Btu/h, is

$$q_s = 60 \times 0.075(0.24 + 0.45\, W)\, Q_s \Delta t \quad (24)$$

where

0.24 = specific heat of dry air, Btu/(lb · °F)
W = humidity ratio, lb water/lb dry air
0.45 = specific heat of water vapor, Btu/(lb · °F)

The specific heats are for a range from about −100 to +200 °F. When $W = 0$, the value of $60 \times 0.075\,(0.24 + 0.45\, W)$ is 1.08; when $W = 0.01$, the value is 1.10; when $W = 0.02$, the value is 1.12; and when $W = 0.03$, the value is 1.14. Thus, since a value of $W = 0.01$ approximates conditions found in many air-conditioning problems, the sensible heat change (Btu/h) can normally be found as

$$q_s = 1.10\, Q_s \Delta t \quad (25)$$

3. Latent heat

Latent heat gain corresponding to the change of humidity ratio (ΔW) for given air flow (standard conditions) Q_s is

$$q_l = 60 \times 0.075 \times 1076\, Q_s \Delta W = 4840\, Q_s \Delta W \quad (26)$$

where 1076 is the approximate heat content of 50% rh vapor at 75 °F, less the heat content of water at 50 °F. The 50% rh at 75 °F is a common design condition for the space, and 50 °F is normal condensate temperature from cooling and dehumidifying coils.

The constants 4.5, 1.10, and 4840 are useful in air-conditioning calculations at sea level (14.7 psia) and for normal temperatures and moisture ratios. For other conditions, more precise values should be used. For an altitude of 5000 ft (12.2 psia), appropriate values are 3.73, 0.92, and 4020.

Latent Heat Gain from Moisture through Permeable Building Materials

The diffusion of moisture through all common building materials is a natural phenomenon that is always present. Chapters 20 and 21 cover the principles and specific methods used to control moisture. Moisture transfer through walls is often neglected in the usual comfort air-conditioning application, because the actual rate is quite small, and the corresponding latent heat gain is insignificant. The permeability and permeance values for various building materials are given in Table 7, Chapter 22. Vapor retarders are frequently installed to keep moisture transfer to a minimum.

Special conditions. Certain industrial applications call for a low moisture content to be maintained in a conditioned space. In such cases, the latent heat gain accompanying moisture transfer through walls may be greater than any other latent heat gain. This gain is computed by

$$q_m = (M/7000)\, A \Delta p_v (h_g - h_f) \quad (27)$$

where

q_m = latent heat gain, Btu/h
M = permeance of wall assembly in perms, or grains/(ft^2 · h · in. Hg)
7000 = grains/lb
A = area of wall surface, ft^2
Δp_v = vapor pressure difference, in. Hg
h_g = enthalpy at room conditions, Btu/lb
h_f = enthalpy of water condensed at cooling coil, Btu/lb
= 1076 Btu/lb when the room temperature is 75 °F and condensate off the coil is 50 °F

Heat Gain from Miscellaneous Sources

The calculation of the cooling load is affected by such factors as (1) type of HVAC system, (2) effectiveness of heat exchange surfaces, (3) fan location, (4) duct heat gain or loss, (5) duct leakage, (6) heat-extraction lighting systems, (7) type of return air system, and (8) sequence of controls. System performance needs to be analyzed as a sequence of individual psychrometric processes. The most straightforward method first defines all known (or desired) state points on a psychrometric chart. Next, the actual entering and leaving dry- and wet-bulb conditions are calculated for such components as the cooling and/or heating coils (based on zone or space load), the amount of outside air introduced into the system through the equipment, and the amount of heat gain or loss at various points.

This overall process must verify that the space conditions originally sought can actually be met by the designed system by considering all sensible and latent heat changes to the air as it travels from the space conditions through the return air system and

equipment back to the conditioned space. If the design is successful (*i.e.*, within the degree of correctness of the various design assumptions), appropriate equipment components can safely be selected. If not, the designer must judge if the results will be "close enough" to satisfy the needs of the project, or if one or more assumptions and/or design criteria must first be modified and the calculations rerun.

Heat gain from fans. Fans that circulate air through HVAC systems add energy to the system by one or all of the following processess:

- Temperature rise in the airstream from fan inefficiency. Depending on the equipment, fan efficiencies generally range between 50 and 70%, with an average value of 65%. Thus, some 35% of the energy required by the fan appears as instantaneous heat gain to the air being transported.
- Temperature rise in the airstream as a consequence of air static and velocity pressure. The "useful" 65% of the total fan energy that creates pressure to move air spreads out throughout the entire air transport system in the process of conversion to sensible heat. Designers commonly assume that the temperature change equivalent of this heat occurs at a single point in the system, depending on fan location as noted below.
- Temperature rise from heat generated by motor and drive inefficiencies. The relatively small gains from fan motors and drives are normally disregarded unless the motor and/or drive are physically located within the conditioned airstream. Equations (15), (16), and (17) may be used to estimate heat gains from typical motors. Belt drive losses are often estimated as 3% of the motor power rating. Conversion to temperature rise is calculated by Equation (25).

The location of each fan relative to other elements (primarily the cooling coil), and the type of system (*e.g.*, single zone, multizone, double-duct, terminal reheat, VAV) along with the concept of equipment control (space temperature alone, space temperature and relative humidity, etc.) must be known before the analysis can be completed. A fan located upstream of the cooling coil (blowthrough supply fan, return air fan, outside air fan) adds the heat equivalent of its inefficiency to the airstream at that point; thus, a slightly elevated entering dry-bulb temperature to the cooling coil results. A fan located downstream of the cooling coil raises the dry-bulb temperature of air leaving the cooling coil. This rise can be offset by reducing the cooling coil temperature, or alternatively, by increasing airflow across the cooling coil as long as its impact on space conditions is considered.

Duct heat gain and leakage. Unless return air duct systems are extensive or subjected to rigorous conditions, only the heat gained or lost by supply duct systems is significant; it is normally estimated as a percentage of space sensible cooling load (usually about 1%) and applied to the dry-bulb temperature of the air leaving the coil in the form of an equivalent temperature reduction.

Duct leakage. Air leakage out of (or into) duct work can have much greater impact than conventional duct heat gain or loss, but it is normally about the same or less. Outward leakage from supply ducts is a direct loss of cooling and/or dehumidifying capacity and must be offset by increased airflow (sometimes reduced supply air temperatures) unless it enters the conditioned space directly. Inward leakage to return ducts causes temperature and/or humidity variations, but these are often ignored under ordinary circumstances due to the low temperature and pressure differentials involved. Chapter 32 has further details on duct sealing and leakage.

A well-designed and installed duct system should not leak more than 1 to 3% of the total system airflow. All HVAC equipment and volume control units connected into a duct system are usually delivered from manufacturers with allowable leakage not exceeding 1 or 2% of maximum airflow rating. Where duct systems are specified to be sealed and leak tested, both low and medium pressure types can be constructed and required to fall within this range, and designers normally assume this loss to approximate 1% of the space load, handled in a similar manner to that for duct heat gain. Latent heat considerations are frequently ignored.

Poorly designed or installed duct systems can have leakage rates of 10 to 30%. Leakage from low-pressure lighting troffer connections lacking proper taping and sealing can be 35% or more of the terminal air supply. Improperly sealed high-pressure systems can leak as much as 10% or more from the high-pressure side alone, before considering the corresponding low-pressure side of such systems. Such extremes destroy the validity of any load calculation procedures. Although not always affecting overall system loads enough to cause problems, they will, however, always adversely impact required supply air quantities for most air-conditioning systems as outlined in Chapter 3 of the 1992 ASHRAE *Handbook—Applications*. Also, using uninsulated supply duct work running through return air plenums results in high "thermal leakage," thus loss of space cooling capability by the supply air, and potential condensation difficulties during a warm startup.

HEATING LOAD PRINCIPLES

Techniques for estimating design heating load for commercial, institutional, and industrial applications are essentially the same as for those estimating design cooling loads for such uses, except that (1) temperatures outside the conditioned spaces are generally lower than the space temperatures maintained; (2) credit for solar heat gains or for internal heat gains is not included; and (3) the thermal storage effect of building structure or content is ignored. Heat losses (negative heat gains) are thus considered to be instantaneous, heat transfer essentially conductive, and latent heat treated only as a function of replacing space humidity lost to the exterior environment.

Justification of this simplified approach derives from the purpose of a heating load estimate, as identification of "worst case" conditions that can reasonably be anticipated during a heating season. Traditionally this is considered as the load that must be met under design interior and exterior conditions, including infiltration and/or ventilation, but in the absence of solar effect (at night or cloudy winter days) and before the periodic presence of people, lights, and appliances can begin to have an offsetting effect. The primary orientation is thus toward identification of adequately sized heating equipment to handle the normal worst-case condition.

Safety factors and load allowances. Before mechanical cooling of buildings became a usual procedure, buildings included much less insulation, large operable windows, and generally more infiltration-prone assemblies than the energy-efficient and much tighter buildings typical of post-1975 design. Allowances of 10 to 20% of the net calculated heating load for piping losses to unheated spaces, and 10 to 20% more for a warm-up load were common practice, along with occasional other safety factors reflecting the experience and/or concern of the individual designer. Such measures are infrequently used in estimating heating loads for contemporary buildings, with the uncompensated net heating load normally considered as having an adequate margin for error.

Cooling needs during noncooling months. Perimeter spaces exposed to high solar heat gain often justify mechanical cooling during sunlit portions of traditional heating months, as will completely interior spaces with significant internal heat gain. These conditions require special attention by the system designer for proper accommodation as needed, but such spaces can also represent significant heating loads during nonsunlit hours or after periods of nonoccupancy when adjacent spaces have been

allowed to cool below interior design temperatures. The loads involved can be estimated conventionally for the purpose of designing the means to offset or to compensate for them and prevent overheating, but they have no direct relationship to design heating loads for the spaces in question.

Other considerations. Calculation of design heating load estimates for this general category of applications has essentially become a subset of the more involved and complex estimation of cooling loads for such spaces. Chapter 28 discusses using the heating load estimate to predict or analyze energy consumption over time. Special provisions to deal with atypical problems are relegated to appropriate chapters in the Systems, Equipment, and Applications volumes.

TRANSFER FUNCTION METHOD CALCULATION PROCEDURE

BASIC COOLING LOAD ANALYSIS

The basic procedures for estimating the maximum design cooling load for a conditioned space were developed when all design calculations were performed manually. For this reason, extensive design analysis was not part of the primary load estimate. Today, with computers used for routine design calculations, the individual load elements may be evaluated more thoroughly and a comprehensive design analysis can be included with the results. The TFM method makes it possible to estimate the cooling load for a conditioned space on an hour-by-hour basis and to predict resultant conditions that can be expected in that space for various system types, control strategies, and operating schedules. The equations and sequence of the TFM Procedure in general are summarized in Table 10.

HEAT GAIN BY CONDUCTION THROUGH EXTERIOR WALLS AND ROOFS

Sensible Heat Gain

The transfer function method (TFM) is particularly well suited for use with a computer. This method is a special case of the calculation of heat flow through building components outlined in Chapter 20. This approach uses (1) sol-air temperature to represent outdoor conditions, and (2) an assumed constant indoor air temperature. Furthermore, both indoor and outdoor surface heat transfer coefficients are assumed constant (Mitalas 1968). Thus, the heat gain through a wall or roof is given by

$$q_{e,\theta} = A\left[\sum_{n=0} b_n (t_{e,\theta-n\delta}) - \sum_{n=1} d_n \{(q_{e,\theta-n\delta})/A\} - t_{rc}\sum_{n=0} c_n\right] \quad (28)$$

where

$q_{e,\theta}$ = heat gain through wall or roof, at calculation hour θ, Btu/h
A = indoor surface area of a wall or roof, ft²
θ = time, h
δ = time interval, h
n = summation index (each summation has as many terms as there are non-negligible values of coefficients)
$t_{e,\theta-n\delta}$ = sol-air temperature at time $\theta - n\delta$, °F
t_{rc} = constant indoor room temperature, °F
b_n, c_n, d_n = conduction transfer function coefficients

Conduction transfer function coefficients. Conduction transfer function (CTF) coefficients are usually calculated using combined outdoor heat transfer coefficient h_o = 3.0 Btu/(h·ft²·°F), indoor coefficient h_i = 1.46 Btu/(h·ft²·°F), and the wall or roof constructions, as may be appropriate. The use of h_o = 3.0 limits the application of these coefficients to cases with similarly calculated sol-air temperature values. Specific CTF coefficients for different constructions can be calculated using the procedure and computer program outlined in Mitalas and Arseneault (1970) or as discussed by the *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992) and with the microcomputer software issued with that publication.

Representative walls and roofs. Harris and McQuiston (1988) investigated the thermal behavior of approximately 2600 walls and 500 roofs as they influenced transmission of heat gain to conditioned spaces. This work identified 41 representative wall assemblies and 42 roof assemblies with widely varying components, insulating values, and mass, and with the predominant mass concentrated near the inside surface (mass in), outside surface (mass out), or essentially homogeneous (mass integral) with the overall construction. These prototypical assemblies can be used to reflect the overall range of conditions. The CTF and associated data pertaining to these conditions are listed in Tables 11 through 19.

Approximate values of CTF coefficients can be obtained by selecting a set of data from Tables 13 and 14 for a roof construction or Tables 18 and 19 for a wall that is nearly the same as the roof or wall under consideration, and multiplying the *b*s and *c*s by the ratio of the U-factor of the roof or wall under consideration over the U-factor of the selected representative roof or wall.

The physical and thermal properties of the various layers that make up roof and wall assemblies are listed in Table 11. Group numbers for various arrangements of layers with differing insulation R value and placement for roofs are listed in Table 12 and those for walls are listed in Tables 15, 16 and 17. Data from these tables identify prototypical roof or wall CTFs and associated data tabulated in Tables 13, 14, 18, and 19.

Example 3. Heat gain through wall. A light-colored wall is constructed of 4 in. heavy concrete, 2 in. insulation (2.0 lb/ft³, R = 6.667 h·ft²·°F/Btu), 3/4 in. indoor plaster, and with outdoor and indoor surface resistances of 0.333 and 0.685 h·ft²·°F/Btu, respectively. There is an air space between the plaster and the insulation. Find the heat gain through 1 ft² of the wall area (*i.e.*, A = 1.0 ft²) with sol-air temperature as listed in Table 1 for July 21, 40° North latitude, West, α/h_0 = 0.15, a room temperature of 75 °F, and assuming that the daily sol-air temperature cycle is repeated on several consecutive days.

Solution: The calculation of heat gain for a particular time requires sol-air temperature values at that and preceding times, as well as the heat flow at preceding times. Heat flow is assumed as zero to start the calculations. The effect of this assumption becomes negligible as the calculation is repeated for successive 24-h cycles.

Sol-Air Temperatures (from Table 1)

Time, h	t_e, °F	Time, h	t_e, °F
1	76	13	110
2	76	14	121
3	75	15	129
4	74	16	131
5	74	17	127
6	75	18	114
7	78	19	87
8	81	20	85
9	85	21	83
10	89	22	81
11	93	23	79
12	97	24	77

and $t_{e,\theta} = t_{e,\theta-24}$ for $\theta > 24$.

Table 10 Summary of TFM Load Calculation Procedures

External Heat Gain

$$t_e = t_o + \alpha I_t/h_o - \epsilon\delta R/h_o \quad (6)$$

$$t_{ea} = t_{oa} + \alpha/h_o\,(I_{DT}/24) - \epsilon\delta R/h_o \quad (7)$$

where

t_e = sol-air temperature
t_o = current hour dry-bulb temperature, from design db (Chapter 24, Table 1) adjusted by Table 2 Daily range % values
α = absorptance of surface for solar radiation
α/h_o = surface color factor—0.15 for light colors, 0.30 for dark
I_t = total incident solar load—1.15 (SHGF), with SHGF per Chapter 27, Tables 12 through 18
$\epsilon\delta R/h_o$ = long-wave radiation factor; −7°F for horizontal surfaces, 0°F for vertical
t_{ea} = 24-h average sol-air temperature
t_{oa} = 24-h average dry-bulb temperature
I_{DT} = total daily solar heat gain (Chapter 27, Tables 12 through 18)

Roofs and Walls

$$q_{e,\theta} = A\left[\sum_{n=o} b_n (t_{c,\theta-n\delta}) - \sum_{n=1} d_n [(q_{e,\theta-n\delta})/A] - t_{rc}\sum_{n=o} c_n\right] \quad (28)$$

where

b and d = conduction transfer coefficients—roof, Table 13; wall, Table 18
c and U_{table} = conduction transfer coefficients—roof, Table 14; wall, Table 19
U_{actual} = design heat transfer coefficient for roof or wall, from Chapter 22, Table 4

Adjust b and c coefficients by ratio U_{actual}/U_{table}.

Roofs

Identify layers of roof construction from Table 11. With R-value of dominant layer, identify R-value Range number R and Roof Group number from Table 12. Proceed to Table 13.

Walls

Identify layers of wall construction from Table 11. With R-value of dominant layer, identify R-value Range number R and Wall Group number from Table 15, 16, or 17. Proceed to Table 14.

θ = hour for which calculation is made
δ = time interval (1 h)
n = number of hours for which b and d values are significant
e = element under analysis, roof or wall assembly
A = area of element under analysis

Glass

$$\text{Convective } q = UA\,(t_o - t_i)$$

$$\text{Solar } q = A\,(\text{SC})(\text{SHGF})$$

U = design heat transfer coefficients, glass—Chapter 27
SC = shading coefficient—Chapter 27
SHGF = solar heat gain factor by orientation, north latitude, hour, and month—Chapter 27, Tables 12 to 18.

Partitions, Ceilings, Floors

$$q = UA\,(t_b - t_i) \quad (8)$$

t_b = temperature in adjacent space
t_i = inside design temperature in conditioned space

Internal Heat Gain

People

$$q_{sensible} = N \times \text{Sensible heat gain}$$

$$q_{latent} = N \times \text{Latent heat gain}$$

N = number of people in space, from best available source. Sensible and latent heat gain from occupancy—Table 3, or Chapter 8; adjust as required.

Lights

$$q_{el} = 3.41\,WF_{ul}F_{sa} \quad (9)$$

where

W = watts input from electrical plans or lighting fixture data
F_{ul} = lighting use factor, from Section 1, as appropriate
F_{sa} = special allowance factor, from Section 1, as appropriate

Power

$$q_p = 2545\,PE_F \quad (15), (16), (17)$$

where

P = horsepower rating from electrical plans or manufacturer's data
E_F = efficiency factors and arrangements to suit circumstances

Appliances

where

$$q_{sensible} = q_{is}F_{ua}F_{ra} \quad (18)$$

or

$$q_{sensible} = (q_{is}F_{ua}F_{ra})/F_{fl} \quad (20)$$

$$q_{latent} = q_{il}F_{ua} \quad (22)$$

q_{is}, q_{il} = sensible and latent heat gain from appliances—Tables 5 to 9, or manufacturer's data (set latent heat = 0, if appliance is under exhaust hood)
F_{ua}, F_{ra}, F_{fl} = use factors, radiation factors, flue loss factors from previous section

Ventilation and Infiltration Air

$$q_{sensible} = 1.10Q\,(t_o - t_i) \quad (25)$$

$$q_{latent} = 4840Q\,(W_o - W_i) \quad (27)$$

$$q_{total} = 4.5Q\,(H_o - H_i) \quad (23)$$

Q = ventilation airflow—ASHRAE *Standard* 62; infiltration cfm—Chapter 23
t_o, t_i = outside, inside air temperature, °F
W_o, W_i = outside, inside air humidity ratio, lb water/lb dry air
H_o, H_i = outside, inside air enthalpy, Btu/lb dry air

Cooling Load

$$\text{Sensible } Q\theta = Q_{tf} + Q_{sc}$$

$$Q_{tf} = \sum_{i=1} (v_o q_{\theta,i} + v_1 q_{\theta,i-\delta} + v_2 q_{\theta,i-2\delta} + \ldots) - (w_1 Q_{\theta-\delta} + w_2 Q_{\theta-2\delta} + \ldots) \quad (31)$$

$$Q_{sc} = \sum_{j=1} (q_{c,j}) \quad (33)$$

Q_{tf} = sensible cooling load from heat gain elements having convective and radiant components
v and w = room transfer function coefficients, Tables 24 and 25; select per element type, circulation rate, mass, and/or fixture type
q_θ = each of i heat gain elements having a radiant component; select appropriate fractions for processing, per Tables 24, 25, and 42
δ = time interval (1 h)
Q_{sc} = sensible cooling load from heat gain elements having only convective components
q_c = each of j heat gain elements having only convective component

$$\text{Latent } Q_l = \sum_{n=1} (q_{c,n})$$

q_c = each of n latent heat gain elements

Table 11 Thermal Properties and Code Numbers of Layers Used in Wall and Roof Descriptions for Tables 12 and 13

[a] Blank spaces denote a roof that is not possible with the chosen combinations of parameters. Numbers 12 through 20 are roof terrace systems. First material is outer layer, second material is inner layer. Massive material numbers are: 4, 5, 6, 7, 8, 9, 12, 13, 14, 15, 16, 17, 18, 19, and 20. Nonmassive material numbers are: 1, 2, 3, 10, and 11.

[b] R-Value ranges in $h \cdot ft^2 \cdot °F/Btu$ are:

No.	Range	No.	Range	No.	Range
1	0 to 5	3	10 to 15	5	20 to 25
2	5 to 10	4	15 to 20	6	25 to 30

CTF Coefficients (Tables 11 and 15 through 19)

Outside surface resistance = A0
4 in. heavyweight concrete = C5
2 in. insulation = B3
Air space resistance = B1
3/4 in. plaster = E1
Inside surface resistance = E0

The appropriate arrangement of layers in the wall can be found in Table 17. The dominant wall layer C5 is at the outside surface ("mass out"), and has a Wall Material column number of 10; combined with an E1 layer, this dictates use of the upper array of code numbers for wall assembly groups. Entering this array with an R-value range of 9 (R = 6.667), column 10 indicates that Wall Group 6 most nearly represents the wall under consideration.

The CTF coefficients of Wall Group 6 as listed in Table 18 are:

b_0	= 0.00051	d_0	= 1.0000
b_1	= 0.00938	d_1	= −1.17580
b_2	= 0.01057	d_2	= 0.30071
b_3	= 0.00127	d_3	= −0.01561
b_4	= 0.00001	d_4	= 0.00001
b_5	= 0.00000	d_5	= 0.00000
b_6	= 0.00000	d_6	= 0.00000

And from Table 19, the U-factor of the wall is 0.199 and $\sum_{n=0} c_n = 0.02174$.

Heat flow calculations. The following format of Equation (28) demonstrates heat flow calculations through the wall:

$$q_{e,\theta}/A = \begin{bmatrix} b_0(t_{e,\theta}) \\ +b_1(t_{e,\theta-\delta}) \\ +b_2(t_{e,\theta-2\delta}) \\ \cdot \\ \cdot \\ \cdot \end{bmatrix} - \begin{bmatrix} d_1[(q_{e,\theta-\delta})/A] \\ +d_2[(q_{e,\theta-2\delta})/A] \\ \cdot \\ \cdot \\ \cdot \\ \cdot \end{bmatrix} - \left[t_{rc} \sum_{n=0} c_n \right]$$

This arrangement indicates that the heat gain through the wall is the sum of three parts:

1. Sum of the products of b coefficients and sol-air temperature values. The current value of this temperature is multiplied by b_0, the sol-air temperature of one step in time earlier is multiplied by b_1, etc.
2. Sum of the products of d coefficients and the previous values of heat gain. Note that the first d used is d_1. Again, the order of values is the same as in the first term, *i.e.*, d_1 is multiplied by the heat gain value that was calculated for the previous step in time, d_2 is multiplied by the value calculated for two steps back in time, etc.
3. A constant, since room air temperature is constant and needs to be calculated only once.

The sequence of calculation using numerical values of this example are then as follows (starting at time θ = 1, expressing heat flux in Btu/(h·ft²), setting A = 1.0, and dropping b and d coefficients 4 through 6 as insignificant):

$$q_{e,1} = \begin{bmatrix} +0.00051(76) \\ +0.00938(77) \\ +0.01057(79) \\ +0.00127(81) \end{bmatrix} - \begin{bmatrix} -1.17580(0) \\ +0.30071(0) \\ -0.01561(0) \end{bmatrix} - [0.02174(75)]$$

$$= 0.068$$

$$q_{e,2} = \begin{bmatrix} +0.00051(76) \\ +0.00938(76) \\ +0.01057(77) \\ +0.00127(79) \end{bmatrix} - \begin{bmatrix} -1.17580(0.068) \\ +0.30071(0) \\ -0.01561(0) \end{bmatrix} - (+1.6305)$$

$$= 0.117$$

The values for q_e for this example are given in the summary table.

The convergence of the heat gain values to a periodic steady-state condition is indicated by comparing the average of the last 24 values with the average heat flow. The latter is given by the product of the U-factor and the difference between the average sol-air and room temperature. Thus

$$q_{avg} = 0.199(91.54 - 75.00) = 3.291 \text{ Btu/(h·ft}^2\text{)}$$

The average of the last 24 values of heat gain tabulated in the summary table is given by:

$$q_{e,avg} = \frac{\sum_{i=73}^{96} q_{e,i}}{24} = \frac{78.954}{24} = 3.290 \text{ Btu/(h·ft}^2\text{)}$$

Note: n is in hours and $q_{e,n}$ is in Btu/(h·ft²).

Heat Gain through Interior Partitions, Floors, and Ceilings

Whenever a conditioned space is adjacent to other spaces at different temperatures, the transfer of heat through the partition can be calculated by:

$$q_{p,\theta} A \left[\sum_{n=0} b_n (t_{b,\theta-n\delta}) - \sum_{n=1} d_n \{(q_{p,\theta-n\delta})/A\} - t_{rc} \sum_{n=0} c_n \right] \quad (29)$$

where

A = area, ft²
t_b = air temperature of adjacent space, °F
b, c, d = CTF coefficients derived from Tables 11 through 19, considering partitions as "walls" and floors or ceilings as "roofs"

Heat gain from adjacent spaces. When t_b is constant or at least the variations of t_b are small compared to the difference ($t_b - t_{rc}$), $q_{p,\theta}$ is given by the simple steady-state expression

$$q_{p,\theta} = UA(t_b - t_{rc}) \quad (30)$$

where U = coefficient of overall heat transfer between the adjacent and the conditioned spaces (see Tables 14 or 19, or Chapter 22).

The same expression gives the mean values for $q_{p,\theta}$, when a mean value of t_b is used even though t_b varies. When $q_{p,\theta}$, is relatively small compared to the other room heat gain components, it may be considered constant at its mean value. If this component

of heat gain is large, the temperature in the adjacent space should be calculated.

Note the common values $q_{p,\theta}$, A, t_b, and t_{rc} in Equations (29) and (30), illustrating the general functional equivalency of CTF coefficients b, c, and d in dynamic heat transfer over time to the steady-state heat transfer coefficient U, thus setting the rationale for adjustment of tabular CTF values by ratio of U_{actual}/U_{table}.

Conversion of Cooling Load from Heat Gain

The cooling load of a space depends on the magnitude and the nature of the sensible heat gain (*i.e.*, heat conduction through walls, direct and diffuse solar radiation, energy input to lights, etc.) and on the location and mass of room objects that absorb the radiant heat. For example, the cooling load profile resulting from a unit pulse of solar radiation absorbed by window glass is quite different from that absorbed by a floor surface. Thus, each component of the room heat gain gives rise to a distinct component of cooling load, and the sum of these various components at any time is the total cooling load at that time.

Unlike other components, the latent heat gain component of the cooling load may or may not be part of room load depending on the type of air-conditioning system, *i.e.*, ventilation air may be dehumidified at a central location rather than in each room.

Cooling load by room transfer function. Stephenson and Mitalas (1967), Mitalas and Stephenson (1967), and Kimura and Stephenson (1968) related heat gain to the corresponding cooling load by a room transfer function (RTF), which depends on the nature of the heat gain and on the heat storage characteristics of the space (*i.e.*, of the walls, floor, etc., that enclose the space, and of the contents of that space). Where the heat gain q_θ is given at equal time intervals, the corresponding cooling load Q_θ at time θ can be related to the current value of q_θ and the preceding values of cooling load and heat gain by:

$$Q_\theta = \sum_{i=1} (v_o q_\theta + v_1 q_{\theta-d} + v_2 q_{\theta-2\delta} + \ldots) - (w_1 Q_{\theta-\delta} + w_2 Q_{\theta-2\delta} + \ldots) \quad (31)$$

where i is taken from 1 to the number of heat gain components and δ = time interval. The terms $v_0, v_1 \ldots, w_1, w_2 \ldots$ are the coefficients of the RTF

$$K_{(z)} = (v_0 + v_1 z^{-1} + v_2 z^{-2} + \ldots)/(1 + w_1 z^{-1} + w_2 z^{-2} + \ldots) \quad (32)$$

which relates the transform of the corresponding parts of the cooling load and of the heat gain. These coefficients depend on (1) the size of the time interval δ between successive values of heat gain and cooling load, (2) the nature of the heat gain (how much is in the form of radiation and where it is absorbed), and (3) on the heat storage capacity of the room and its contents. Therefore, different RTFs are used to convert each distinct heat gain component to cooling load.

While the basic form of Equation (31) anticipates a series of v_n and w_n coefficients, the effect of past v_1 and w_1 is negligible, and data tabulated may generally be used with confidence. A slight inaccuracy does occur in the calculation for the first hour that internal loads begin; up through the second before the hour for which the calculation is made, such load does not exist, and the value generated by the transfer functions is not reached until the end of that hour. The convective component of such load is instantaneous, and the growth of the radiant component (combined with the convective element by the transfer coefficients) as it is absorbed and released by the building mass and contents is realistic throughout the rest of the load period.

Sensitivity of Parameters—Nontypical Applications

The concept of evaluating the thermal storage performance of a given space by means of RTF coefficients is based on the essential similarity of enclosing surfaces, spacial geometry, and related characteristics of that space to corresponding parameters of the space for which the data were calculated. ASHRAE research projects 359-RP [(Chiles and Sowell 1984), (Sowell and Chiles 1984a),

Table 20 Zone Parametric Level Definitions

No.	Parameter	Meaning	Levels (in normal order)
1	ZG	Zone geometry	100 ft × 20 ft, 15 ft × 15 ft 100 ft × 100 ft
2	ZH	Zone height	8 ft, 10 ft, 20 ft
3	NW	No. exterior walls	1, 2, 3, 4, 0
4	IS	Interior shade	100, 50, 0%

2	Outside surface resistance, 1 in. stucco, 8 in. HW concrete, 3/4 in. plaster or gypsum, inside surface resistance (A0, A1, C10, E1, E0)
3	Outside surface resistance, steel siding, 3 in. insulation, steel siding, inside surface (A0, A3, B12, A3, E0)*
4	Outside surface resistance, 4 in. face brick, 2 in. insulation. 12 in. HW concrete, 3/4 in. plaster or gypsum, inside surface resistance (A0, A2, B3, C11, E1, E0)*

Note: Code letters are defined in Table 11.

Table 22 Floor and Ceiling Types Specified by Zone Location Parameter

Zone Location	Floor	Ceiling
Single story	Slab-on-grade	Roof
Top floor	Mid-floor	Roof
Bottom floor	Slab-on-grade	Mid-floor
Mid-floor	Mid-floor	Mid-floor

Table 23 Roof Construction Types

Type	Description
1	Outside surface resistance, 1/2 in. slag or stone, 3/8 in. felt membrane, 1 in. insulation, steel siding, inside surface resistance (A0, E2, E3, B4, A3, E0)*
2	Outside surface resistance, 1/2 in. slag or stone, 3/8 in. felt membrane, 6 in. LW concrete, inside surface resistance (A0, E2, E3, C15, E0)*
3	Outside surface resistance, 1/2 in. slag or stone, 3/8 in. felt membrane, 2 in. insulation, steel siding, ceiling air space, acoustic tile, inside surface resistance (A0, E2, E3, B6, A3, E4, E5, E0)*
4	Outside surface resistance, 1/2 in. slag or stone, 3/8 in. felt membrane, 8 in. LW concrete, ceiling air space, acoustic tile, inside surface resistance (A0, E2, E3, C16, E4, E5, E0)*

Note: Code letters are defined in Table 11.

(Sowell and Chiles 1984b)], 472-RP [(Harris and McQuiston 1988), (Sowell 1988a), (Sowell 1988b), (Sowell 1988c)], and 626-RP [(Falconer *et al.* 1993), (Spitler and McQuiston 1993), (Spitler *et al.* 1993)] investigated the unexpected sensitivity of such attributes and other counterintuitive phenomena regarding apparent responsiveness of relative masses in the storage and rejection of heat, and identified 14 discrete screening parameters with two to five levels of characterization each (Tables 20 through 23) by which to select representative data and to modify factors appropriately for specific applications. While these selection parameters are arranged so that errors due to deviations are minimal and conservative, careful use is required in situations differing significantly from one or more specific parameters.

Peak heat gain versus peak cooling load. The RTF procedure distributes all heat gained during a 24-h period throughout that period in the conversion to cooling load. Thus, individual heat gain components rarely appear at full value as part of the cooling load unless representing a constant 24-h input (such as a continuously burning light fixture), or in very low mass construction that releases stored radiant heat relatively quickly. This concept is further complicated by the premise of "constant interior space temperature" (*i.e.*, operation of an HVAC system 24 h a day, seven days a week with fixed control settings), which practice is far less prevalent today than in the past. The effect of intermittent system operation is seen primarily during the first hours of operation for a subsequent day, as discussed in the section Heat Extraction Rate, and can impact equipment size selection significantly.

Superposition of load components. Finally, a presupposition of the TFM is that total cooling load for a space can be calculated by simple addition of the individual components. For example, radiation heat transfer from individual walls or roofs is assumed to be independent of the other surfaces, which is slightly incorrect in a theoretical sense. However, extensive ASHRAE sponsored research found that the means for compensation for these limitations fall within the range of acceptable error that must be expected in any estimate of cooling load.

The abovementioned research calculated RTF values for all possible combinations of screening parameter levels for a total of 200,640 individual cases. Access to these data is available electronically by techniques outlined in the Cooling and Heating Load Calculation Manual (McQuiston and Spitler 1992). For illustration of the TFM, a simplified method of RTF selection is presented in this chapter with RTF coefficients for various types and configurations of room construction and room air circulation rates given in Tables 24 and 25.

Table 24 Room Transfer Functions: w Coefficient

Room Air Circulation[a] and S/R Type	Room Envelope Construction[b]: 2-in. Wood Floor	3-in. Concrete Floor	6-in. Concrete Floor	8-in. Concrete Floor	12-in. Concrete Floor
	Specific Mass per Unit Floor Area, lb/ft²				
	10	40	75	120	160
Low	−0.88	−0.92	−0.95	−0.97	−0.98
Medium	−0.84	−0.90	−0.94	−0.96	−0.97
High	−0.81	−0.88	−0.93	−0.95	−0.97
Very High	−0.77	−0.85	−0.92	−0.95	−0.97
	−0.73	−0.83	−0.91	−0.94	−0.96

[a]Circulation rate—
Low: Minimum required to cope with cooling load from lights and occupants in interior zone. Supply through floor, wall, or ceiling diffuser. Ceiling space not used for return air, and h = 0.4 Btu/h · ft² · °F (where h = inside surface convection coefficient used in calculation of w_1 value).
Medium: Supply through floor, wall, or ceiling diffuser. Ceiling space not used for return air, and h = 0.6 Btu/h · ft² · °F.
High: Room air circulation induced by primary air of induction unit or by room fan and coil unit. Ceiling space used for return air, and h = 0.8 Btu/h · ft² · °F.
Very high: High room circulation used to minimize temperature gradients in a room. Ceiling space used for return air, and h = 0.8 Btu/h · ft² · °F.
[b]Floor covered with carpet and rubber pad; for a bare floor or if covered with floor tile, take next w_1 value down the column.

Use of Room Transfer Functions

To obtain appropriate room transfer function data for use in Equation (31), (1) select the value of w_1 from Table 24 for the approximate space envelope construction and range of air circulation, and (2) select and/or calculate the values of v_0 and v_1 from

Table 25 Room Transfer Functions: v_0 and v_1 Coefficients

Heat Gain Component	Room Envelope Construction[b]	v_0 Dimensionless	v_1 Dimensionless
Solar heat gain through glass[c] with no interior shade; radiant heat from equipment and people	Light	0.224	$1+w_1-v_0$
	Medium	0.197	$1+w_1-v_0$
	Heavy	0.187	$1+w_1-v_0$
Conduction heat gain through exterior walls, roofs, partitions, doors, windows with blinds or drapes	Light	0.703	$1+w_1-v_0$
	Medium	0.681	$1+w_1-v_0$
	Heavy	0.676	$1+w_1-v_0$
Convective heat generated by equipment and people, and from ventilation and infiltration air	Light	1.000	0.0
	Medium	1.000	0.0
	Heavy	1.000	0.0

Heat Gain from Lights[d]

Furnishings	Air Supply and Return	Type of Light Fixture	v_0	v_1
Heavyweight simple furnishings, no carpet	Low rate; supply and return below ceiling ($V \leq 0.5$)[c]	Recessed, not vented	0.450	$1+w_1-v_0$
Ordinary furnishings, no carpet	Medium to high rate, supply and return below or through ceiling ($V \geq 0.5$)[c]	Recessed, not vented	0.550	$1+w_1-v_0$
Ordinary furnishings, with or without carpet on floor	Medium to high rate, or induction unit or fan and coil, supply and return below, or through ceiling, return air plenum ($V \geq 0.5$)[c]	Vented	0.650	$1+w_1-v_0$
Any type of furniture, with or without carpet	Ducted returns through light fixtures	Vented or free-hanging in airstream with ducted returns	0.750	$1+w_1-v_0$

[a]The transfer functions in this table were calculated by procedures outlined in Mitalas and Stephenson (1967) and are acceptable for cases where all heat gain energy eventually appears as cooling load. The computer program used was developed at the National Research Council of Canada, Division of Building Research.
[b]The construction designations denote the following:
Light construction: such as frame exterior wall, 2-in. concrete floor slab, approximately 30 lb of material/ft² of floor area.
Medium construction: such as 4-in. concrete exterior wall, 4-in. concrete floor slab, approximately 70 lb of building material/ft² of floor area.
Heavy construction: such as 6-in. concrete exterior wall, 6-in. concrete floor slab, approximately 130 lb of building material/ft² of floor area.
[c]The coefficients of the transfer function that relate room cooling load to solar heat gain through glass depend on where the solar energy is absorbed. If the window is shaded by an inside blind or curtain, most of the solar energy is absorbed by the shade, and is transferred to the room by convection and long-wave radiation in about the same proportion as the heat gain through walls and roofs; thus the same transfer coefficients apply.
[d]If room supply air is exhausted through the space above the ceiling and lights are recessed, such air removes some heat from the lights that would otherwise have entered the room. This removed light heat is still a load on the cooling plant if the air is recirculated, even though it is not a part of the room heat gain as such. The percent of heat gain appearing in the room depends on the type of lighting fixture, its mounting, and the exhaust airflow.
[e]V is room air supply rate in cfm/ft² of floor area.

Table 25 for the appropriate heat gain component and range of space construction mass.

Example 4. Cooling load due to solar radiation through glass. Consider a room having a 1/2 in. air space double-glazed window (shading coefficient = 0.83) in a multistory office building of heavyweight construction (approximately 120 lb/ft² floor area). The building is located at 40°N latitude, the date is June 21, and the window orientation is NW. The U-factor for the window is 0.56 Btu/(h·ft²·°F). Assume the floor to be carpeted, the air circulation rate "medium" (h_i = 0.6 Btu/(h·ft²·°F), and the ceiling space not ventilated. Calculate the cooling load due to solar radiation through glass. Solar heat gain (SHG) to the room through the window is given as SHG = SHGF × Shading Coefficient = SHGF × 0.83.

Time, h	SHGF	SHG	Time, h	SHGF	SHG
0100	0	0	1300	40	33
0200	0	0	1400	63	52
0300	0	0	1500	114	95
0400	0	0	1600	156	129
0500	1	1	1700	172	143
0600	13	11	1800	143	119
0700	21	17	1900	21	17
0800	27	22	2000	0	0
0900	32	27	2100	0	0
1000	35	29	2200	0	0
1100	38	32	2300	0	0
1200	38	32	2400	0	0
Daily total					753

Note: SHGF from Table 15, Chapter 27.

Solution: The room transfer function coefficients for 120 lb/ft² construction, solar radiation input, medium air circulation rate, and the condition of "no heat loss for the room" are (see Tables 24 and 25):

$$v_0 = 0.187 \qquad w_0 = 1.000 \text{ (in all cases)}$$
$$v_1 = -0.147 \qquad w_1 = -0.960$$

The cooling load component due to solar radiation through glass at any time θ is given by Equation (31). The calculations can be set up as follows:

$$Q_\theta = \begin{bmatrix} v_0(\text{SHG}_\theta) \\ + v_1(\text{SHG}_{\theta-\delta}) \\ - w_1(Q_{\theta-\delta}) \end{bmatrix}$$

As in the earlier heat gain calculation example, the calculation is started by assuming that the previous Qs are zero. Furthermore, in this example, SHG = 0 for θ = 1, 2, 3, and 4; therefore, Qs in Btu/(h·ft²) are:

Q_5	v, w	Hour	SHG	Prev. Qs	Factor
	0.187	5	1		0.187
	−0.147	4	0		0.000
	0.96	4		0	0.000
				Q_5 =	0.187
Q_6	v, w	Hour	SHG	Prev. Qs	Factor
	0.187	6	11		0.187
	−0.147	5	1		−0.147
	0.96	5		0.187	0.180
				Q_6 =	2.090

Values of Q_θ for the remainder of the calculations are listed in the following table. The calculations of Q_θ are terminated at θ = 96 h, because by that time, the effect of the assumed zero initial conditions has decreased to negligible proportions.

Values of Q_θ for Example 4

θ	Q_θ	θ	Q_θ	θ	Q_θ	θ	Q_θ
1 =	0.000	25 =	17.041	49 =	23.440	73 =	25.842

22 =	19.261	46 =	26.494	70 =	29.209	94 =	30.228
23 =	18.491	47 =	25.434	71 =	28.041	95 =	29.019
24 =	17.751	48 =	24.417	72 =	26.919	96 =	27.858

Note: Values carried to 3 decimals to illustrate degree of convergence.

Cooling Load from Nonradiant Heat Gain

Sensible cooling load from strictly convective heat gain elements is instantaneous, added directly to the results of those gains processed by CTF and RTF coefficients, per the following equation.

$$Q_{sc} = \sum_{j=1} (q_{c,j}) \tag{33}$$

where

Q_{sc} = sensible cooling load from heat gain elements having only convective components
q_c = each of j heat gain elements having only such convective component

Heat Extraction Rate and Room Temperature

Discussion to this point has concentrated on estimating design cooling load for a conditioned space, assuming the maintenance of a constant interior temperature and the hourly total removal of all cooling load entering the space; and allowing the delaying action of building mass and contents to run its course. Certain minor factors have been ignored, such as the relatively indeterminate radiant heat loss to the outside of the building.

The basic principles of the TFM are also useful in estimating dynamic cooling load requirements over an extended period (see Chapter 28). In such cases, however, the goal is no longer to seek the peak load for equipment selection purposes, and the ebb and flow of heat into and out of the building assume much greater importance; thus, any loss back to the environment must be considered. This concept is also critical in predicting temperature swings in the space and the ability of cooling equipment to extract heat when operated in a building with extended off cycles (nights and weekends).

The cooling loads determined by the TFM serve as input data for estimating the resultant room air temperature and the heat extraction rate with a particular type and size of cooling unit, or set of operating conditions, or both. In addition, the characteristics of the cooling unit (*i.e.*, heat extraction rate versus room air

temperature), the schedule of operation, and a space air transfer function (SATF) for the room that relates room air temperature and heat extraction rate must also be included to run these calculations.

The heat extraction characteristics of the cooling unit can be approximated by a linear expression of the form

$$ER_\theta = W_\theta + (St_{r\theta}) \quad (34)$$

where

ER_θ = rate of heat removal from space at time θ
$t_{r\theta}$ = the air temperature in space at time θ
W, S = parameters characterizing performance of specific types of cooling equipment

This linear relationship only holds when $t_{r\theta}$ is within the throttling range of the control system. When $t_{r\theta}$ lies outside of this range, ER_θ has the value of either ER_{max} or ER_{min}, depending on whether the temperature $t_{r\theta}$ is above or below the throttling range. The value of S is the difference $ER_{max} - ER_{min}$ divided by the width of the throttling range, and W_θ is the value ER_θ would have if the straight-line relationship between it and $t_{r\theta}$ held at t_{r1} equals zero. This intercept depends on the set point temperature of the control system, which may be taken as the temperature at the middle of the throttling range. Thus,

$$W_\theta = (ER_{max} + ER_{min})/2 - (St^*_{r\theta}) \quad (35)$$

where $t^*_{r\theta}$ is the thermostat set point temperature at time θ.

Space Air Transfer Function

The heat extraction rate and the room air temperature are related by the space air transfer function (SATF):

$$\sum_{i=0}^{1} p_i(ER_{\theta-\delta} - Q_{\theta-i\delta}) = \sum_{i=0}^{2} g_i(t_{rc} - t_{r,\theta-i\delta}) \quad (36)$$

where g_1 and p_1 are the SATF coefficients, and Q is the calculated cooling load for the room at time θ, based on an assumed constant room temperature of t_{rc}. Normalized values of g and p are given in Table 26 for light, medium, and heavy construction.

Thermal conductance to surroundings. In calculating the design cooling load components previously described, it was assumed that all energy transferred into the space eventually appears as space cooling load. However, this is not quite true over an extended period, because a fraction of the input energy can instead be lost back to the surroundings. This fraction F_c depends on the thermal conductance between the space air and the surroundings and can be estimated as

$$F_c = 1 - 0.02\,K_\theta \quad (37)$$

Table 26 Normalized Coefficients of Space Air Transfer Functions[a]

Room Envelope Construction[b]	g_0*	g_1*	g_2*	p_0	p_1
	Btu/h · ft² · °F			Dimensionless	
Light	+1.68	−1.73	+0.05	1.0	−0.82
Medium	+1.81	−1.89	+0.08	1.0	−0.87
Heavy	+1.85	−1.95	+0.10	1.0	−0.93

[a]For simplified procedure for calculating space air transfer function coefficients, see ASHRAE (1975).
[b]The designations Light, Medium, and Heavy denote the same meanings as those footnoted for Table 25.

where K_θ is the unit length conductance between the space air and surroundings, in Btu/(h · ft² · °F), given by

$$K_\theta = (1/L_F)(U_R A_R + U_W A_W + U_{OW} A_{OW} + U_P A_P) \quad (38)$$

where

L_F = length of space exterior wall, ft
U = U-factor of space enclosure element (subscript R for roof, W for window, OW for outside wall, and P for partition, should such be adjacent to an unconditioned area), Btu/(h · ft² · °F)
A = area of space enclosure element, ft²

The units of K_θ are Btu/(h · ft² · °F). Therefore, if F_c is to be dimensionless, the multiplier is 0.02 h · ft² · °F/Btu.

Adjustment of load components. To adjust the space cooling loads calculated in the previous sections, multiply the value of the following components by the factor F_c from Equation (37):

- Sensible cooling load from heat gain by conduction through exterior roofs and walls
- Sensible cooling load from conduction and solar heat gain through fenestration areas
- Sensible cooling load from heat gain through interior partitions, ceilings, and floors
- Sensible cooling load from radiant portion of heat gain from lights, people, and equipment

Adjustments to g coefficients.* To obtain the SATF coefficients for Equation (36), first select the values of p_0, p_1, g_0*, g_1*, and g_2* from Table 26 for the appropriate space envelope construction. Since the g* coefficients in Table 26 are for a space with zero heat conductance to surrounding spaces and are normalized to a unit floor area, it is necessary to adjust the 0 and 1 values. To get the g_0 and g_1 coefficients for a space with a floor area A, total conductance K_θ [by Equation (38)] between space air surroundings, ventilation rate, and infiltration rate, the relationships are:

$$g_{0,\theta} = g_0^* A + p_0\,[K_\theta + 1.10\,(V_\theta + VI_\theta)] \quad (39)$$

$$g_{1\theta} = g_1^* A + p_1\,[K_\theta + 1.10\,(V_{\theta-1\delta} + VI_{\theta-1\delta})] \quad (40)$$

Note that Equation (40) has no second term when calculating $g_{2,\theta}$, since p_2 has no value.

Heat extraction rate. For either condition (heat loss to surroundings or not, and using the appropriate values of g), Equations (34) and (35) can be solved simultaneously for ER_θ

$$ER_\theta = [W_\theta g_0/(S + g_0)] + [I_\theta S/(S + g_0)] \quad (41)$$

where

$$I_\theta = t_{rc}\sum_{i=0}^{2} g_{i,\theta} - \sum_{i=1}^{2} g_{i,\theta}(t_{r,\theta-i\delta}) + \sum_{i=0}^{1} p_i\,(Q_{\theta-i\delta}) - \sum_{i=1}^{1} p_i(ER_{\theta-i\delta}) \quad (42)$$

If the value of ER_θ calculated by Equation (41) is greater than ER_{max}, it is made equal to ER_{max}; if it is less than ER_{min}, it is made equal to ER_{min}. Then $t_{r\theta}$ is calculated from the expression

$$t_{r\theta} = (1/g_{0,\theta})(I_\theta - ER_\theta) \quad (43)$$

Example 5. Calculation of room air temperature and heat extraction rate. A room is of heavy construction with a floor area of 400 ft². The total room cooling load calculated on the basis of $t_{rc} = 70$°F is given as:

θ, h	Q_θ, Btu/h	θ, h	Q_θ, Btu/h	θ, h	Q_θ, Btu/h
1	2200	9	2180	17	7630
2	2030	10	2330	18	6880
3	1850	11	2650	19	5530
4	1730	12	3580	20	4380
5	1680	13	4880	21	3630
6	1750	14	6180	22	3130
7	1880	15	7150	23	2730
8	2030	16	7680	24	2450

The cooling unit has a maximum heat extraction capability of 7500 Btu/h and a minimum of zero. The throttling range is 3 °F wide. Assume no ventilation and no infiltration, and heat loss to the exterior surroundings at the rate of 100 Btu/(h·°F). Calculate room air temperature and heat extraction rate for:

Schedule A. The control thermostat is set at 77 °F from 0700 to 1800 h; during the rest of the time, it is set up to 85 °F.

Schedule B. The control thermostat is set at 77 °F all the time.

Solution:

(a) Space Air Transfer Functions.

The SATF coefficients for a 400-ft² room of heavy construction are [from Table 22 and Equations (39) and (40) with V and V_1 dropping out]:

$$g_{0,\theta} = 400(+1.85) + 100(+1.0) = 840.00$$
$$g_{1,\theta} = 400(-1.95) + 100(-0.93) = -873.00$$
$$g_{2,\theta} = 400(+0.10) = 40.00$$
$$\sum_{i=0}^{2} g_i = 7.00$$

(b) Cooling Unit Characteristics.

$ER_{max} = 7500$ Btu/h

$ER_{min} = 0$

$t_{tr} = 3$ °F throttling range

$S = (7500 - 0)/3 = 2500$ Btu/(h·°F)

when $t^*_{r\theta} = 77.0$ °F,

$$W_\theta = [(7500 - 0)/2] - 2500(77.0) = -188{,}750 \text{ Btu/h}$$

and when $t^*_{r\theta} = 85.0$ °F,

$$W_\theta = [(7500 - 0)/2] - 2500(85.0) = -208{,}750 \text{ Btu/h}$$

(c) Calculation of ER_θ and $t_{r\theta}$.

Some prior values for ER_θ and $t_{r\theta}$ must be assumed to begin the computation process. The computation is repeated until the results for successive days are the same. At that time, the results are independent of the values assumed initially.

To get the calculation started, assume all previous values of $ER = 0$ and $t_r = 80$ °F. Thus:

$$I_1 = 70.0(7.0) - \begin{bmatrix} -873\ (80) \\ +40\ (80) \end{bmatrix} + \begin{bmatrix} +1.0\ (2200) \\ -0.93\ (2450) \end{bmatrix} - \begin{bmatrix} -0.93\ (0.0) \end{bmatrix}$$

$$= 67{,}052 \text{ Btu/h}$$

$$ER_1 = (-208{,}750)\ 840/(2500 + 840) + (67{,}052)\ 2500/(2500 + 840)$$
$$= -52{,}500 + 50{,}189 = -2311 \text{ Btu/h}$$

As this is less than ER_{min}, $ER_1 = ER_{min} = 0.0$

and $t_{r1} = (1/840)(67{,}052 - 0.0) = 79.8$ °F

Table 27 Room Air Temperature and Heat Extraction Rates for Example 6

	Schedule A (Control thermostat set at 77 °F from 0800 to 1800, and at 85 °F at all other times)		Schedule B (Control thermostat set at 77 °F at all times)	
Time, h	Room Air Temperature t_r, °F	Heat Extraction ER, Btu/h	Room Air Temperature t_r, °F	Heat Extraction ER, Btu/h
0100	82.0	0	76.3	1956
0200	81.9	0	76.2	1806
0300	81.8	0	76.2	1649
0400	81.7	0	76.1	1535

0800	77.2	4235	76.2	1680
0900	77.1	4051	76.2	1780
1000	77.1	4025	76.3	1881
1100	77.2	4138	76.3	2113
1200	77.4	4720	76.6	2807
1300	77.7	5602	77.0	3794
1400	78.1	6507	77.4	4799
1500	78.4	7184	77.7	5571
1600	78.6	7500	77.9	6019
1700	78.5	7477	77.9	6032
1800	78.3	6876	77.7	5513
1900	83.8	786	77.3	4528
2000	83.6	268	77.0	3669
2100	83.3	0	76.7	3099
2200	82.8	0	76.6	2710
2300	82.5	0	76.5	2393
2400	82.3	0	76.4	2164
	Totals	63369		72061

$$I_2 = 70.0(7.0) - \begin{bmatrix} -873\ (79.8) \\ +40\ (80) \end{bmatrix} + \begin{bmatrix} +1.0\ (2030) \\ -0.93\ (2200) \end{bmatrix} - \begin{bmatrix} -0.93\ (0.0) \end{bmatrix}$$

$$= 66{,}939 \text{ Btu/h}$$

$$ER_2 = (-208{,}750)\ 840/(2500 + 840) + (66{,}939)\ 2500/(2500 + 840)$$
$$= -52{,}500 + 50{,}104 = -2396 \text{ Btu/h}$$

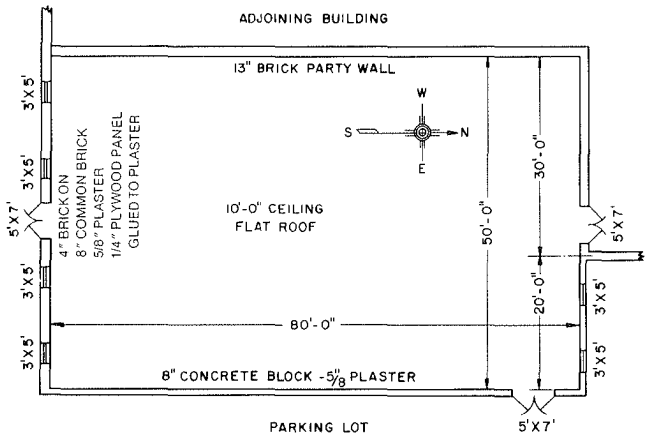
As this also is less than ER_{min}, $ER_2 = ER_{min} = 0$ and $t_{r2} = (1/840)(66{,}939 - 0) = 79.7$ °F, and so on.

The effect of the assumed initial ER_θ and $t_{r\theta}$ values has decreased to negligible proportions by the time $\theta = 145$, *i.e.*, $t_{r145} = t_{r169} = 82.6$ °F. The complete set of results for operating schedules A and B is given in Table 27.

EXAMPLE COOLING LOAD CALCULATION

Example 6. Cooling load calculation of small office building. A one-story small commercial building (Figure 4) is located in the eastern United States near 40 °N latitude. The adjoining buildings on the north and west are not conditioned, and the air temperature within them is approximately equal to the outdoor air temperature at any time of day.

Note: The small commercial building shown in Figure 4 has been in the ASHRAE literature for several decades to illustrate cooling load procedures. In this example, some materials have been updated to reflect currently available products and associated U-factors, and the calculation month changed to July for better comparison with newer data. Otherwise, all other characteristics of this example remain unchanged.



Note: The small commercial building shown in this figure has been in the ASHRAE literature for several decades to illustrate cooling load procedures. In this example, some materials have been updated to reflect currently available products and associated U-factors; the calculation month has been changed to July for better comparison with newer data. Otherwise, all other characteristics of this example remain unchanged.

Fig. 4 Plan of One-Story Office Building

Building Data:

South wall construction. 4-in. light-colored face brick, 8-in. common brick, 0.625-in. plaster, 0.25-in. plywood panel glued on plaster (Summer $U = 0.24$ Btu/h·ft²·°F, or $R = 4.14$).

East wall and outside north wall construction. 8-in. light-colored heavy concrete block, 5/8-in. plaster on walls (Summer $U = 0.48$ Btu/h·ft²·°F, or $R = 2.083$).

West wall and adjoining north party wall construction. 13-in. solid brick (color N/A), no plaster: with U for a 12-in. brick interior wall = 0.26, R for that wall = 1/0.26 = 3.846; subtracting 2 still air film coefficients with $R_{fc} = 0.68$ each leaves $R_b = 2.486$; thus for this wall:

$$R_w = 0.68 + (2.486 \times 13/12) + 0.68 = 4.053$$

and

$$U_w = 1/4.053 = 0.247, \text{ say } U = 0.25 \text{ Btu/(h·ft²·°F)}$$

Roof construction. 4-1/2-in. (nominal) flat roof of 2-in. gypsum slab on metal roof deck, 2-in. rigid roof insulation, surfaced with two layers of mopped 15-lb felt vapor-seal built-up roofing having dark-colored gravel surface, and with no false ceiling below underside of roof deck; (Summer $U = 0.09$ Btu/h·ft²·°F, or $R = 11.11$).

Floor construction. 4-in. concrete on ground.

Fenestration. 3 ft by 5 ft nonoperable windows of regular plate glass with light colored venetian blinds (Summer $U = 0.81$ Btu/h·ft²·°F).

Door construction. Light-colored 1.75-in. steel door with solid urethane core and thermal break (Summer $U = 0.19$ Btu/h·ft²·°F or $R = 5.26$ for exterior doors, and $U = 0.18$ Btu/h·ft²·°F or $R = 5.56$ for interior doors).

Front doors. Two 30 in. by 7 ft

Side doors. Two 30 in. by 7 ft

Rear doors. Two 30 in. by 7 ft (interior)

Note: U-factors for all exterior surfaces assume a summer wind velocity of 7.5 mph. Those for party walls and other interior surfaces assume still air.

Summer outdoor design conditions. Dry bulb 94 °F, daily range 20 °F, wet bulb 77 °F: $W_o = 0.0161$ lb vapor/lb dry air; $h_o = 40.3$ Btu/lb dry air.

Winter outdoor design conditions. Dry bulb 10 °F.

Summer indoor design conditions. Dry bulb 75 °F, wet bulb 62.5 °F; $W_i = 0.0092$ lb vapor/lb dry air; $h_i = 28.07$ Btu/lb dry air.

Winter indoor design conditions. Dry bulb 75 °F.

Occupancy. 85 office workers from 0800 to 1700 h.

Lights. 17,500 watts, fluorescent, operating from 0800 to 1700 hours daily; along with 4000 watts, tungsten, operated continuously. Lighting fixtures are non-ventilated type.

Power equipment and appliances. For this example, none are assumed.

Ventilation. From ASHRAE *Standard* 62, a ventilation rate of 15 cfm/person is selected as representative of a drugstore or hardware store. With 85 people, the total ventilation air quantity is thus 1275 cfm. Floor area of 4000 ft² with 10 ft ceiling height gives a space volume of 40,000 ft³, corresponding to (1275 cfm × 60)/40,000 = 1.91 air changes/h. In practice, ventilation air is normally conditioned to some extent by the air conditioning equipment before being admitted to the conditioned space. However, the variety of such arrangements and the varying impact felt by the load calculation process are not covered by this chapter and should be evaluated as part of a system analysis procedure. For this example, assume the ventilation air is introduced directly into the space and included as part of the space cooling load, but only during scheduled operating hours of the cooling equipment.

Infiltration. Window infiltration is considered zero, since the windows are sealed. Infiltration through wall surfaces is also neglected as insignificant, particularly with plastered interior surfaces. Calculation of door infiltration however, requires some judgement. The pressure of 1.91 air changes/h in the form of positive ventilation could be sufficient to prevent door infiltration, depending on the degree of simultaneous door openings and the wind direction and velocity. For this example, assume that outside and inside doors are frequently opened simultaneously, and that door infiltration should be included as part of the cooling load, estimating 100 ft³ per person per door passage. Further estimating outside door use at 10 persons/h, and inside doors (to unconditioned space, previously estimated to be at ambient temperature and humidity) at 30 persons/h, generates the following infiltration rate:

$$Q_{inf} = 40 \times 100/60 = 67 \text{ cfm}$$

Thermal responsiveness of building and contents. For this example, mass of building construction and contents is "medium."

Conditioning equipment location. Conditioning equipment is in an adjoining structure to the north, thus having no direct impact on heat gain.

Find:

1. Sensible cooling load.
2. Latent cooling load.
3. Total cooling load.
4. Capacity of system to maintain:
   (a) Fixed temperature: 75 °F indoor temperature, 24-hour "on" period.
   (b) 2 °F throttling range: Indoor temperature in the range 75 to 77 °F, 24-hour "on" period.
   (c) 4 °F throttling range: Indoor temperature in the range 75 to 79 °F, 24-hour "on" period.
   (d) 2 °F throttling range: Indoor temperature in the range 75 to 77 °F, 10-hour "on" period, 0800 to 1700.
   (e) 4 °F throttling range: Indoor temperature in the range 75 to 79 °F, 12-hour "on" period, 0600 to 1700.

Solution by Transfer Function Method

1. Daily load cycle: Estimated thermal loads are calculated by the TFM once per hour for a 24-h daily cycle.
2. Hourly heat gain components: The methodology using CTF coefficients is used to calculate heat gain components through walls and roof.
3. Thermal storage: The heat storage effect of the building and contents is accounted for by RTF coefficients.
4. Room temperature and heat extraction: TFM approximates resultant room air temperature and heat extraction rates for a specified schedule of thermostat set-points and/or cooling unit operating periods, by applying SATF coefficients to sensible cooling loads, including consideration for heat loss to surroundings. This process can be used to predict the capability of a particular size and type of cooling equipment, its control, and its operating schedule to maintain room air temperature within a specified range.
5. Summary: The data and summary of results using TFM are tabulated in Table 28. The following describes the calculation procedure used to determine the values for this table:

1. Sensible cooling load

(a) General

Line 1, Time of day in hours: Various temperatures and heat flow rates were calculated for every hour on the hour, assuming that hourly values are sufficient to define the daily profile.

Line 2, Outside air temperatures: Hourly values derived by the above-mentioned procedure, using the specified maximum dry bulb temperature of 94 °F and daily range of 20 °F.

(b) Solar heat gain factors

Lines 3, 4, 5, and 6, Solar heat gain through opaque surfaces: SHGF values from Table 15, Chapter 27 for July 21 at 40 °N latitude. These values are used to calculate sol-air temperatures of various outside surfaces, and solar heat gain through windows.

Values for June might have been used, since the solar irradiation of horizontal surface (*e.g.*, a roof) is maximum at that time of year and since the heat gain through the roof appears to be the major component of exterior heat gain in this problem. The difference between June and August values is relatively small however, compared to the large percentage increase in solar heat gain through south glass in August versus June at this latitude, thus indicating that August might be the better choice. For this example, data for July were selected as reasonable, and to provide better comparison with the results from other techniques for which tabular data are limited. To determine the month when the maximum building load will occur, the relative loads of various surfaces should first be evaluated and compared for several months.

(c) Sol-air temperatures

Lines 7, 8, 9, and 10, Sol-air temperatures at opaque surfaces: Sol-air temperatures, calculated by Equation (6), of the various opaque surfaces. These values are used in calculations of heat gain through the roof and outside walls.

(d) Instantaneous sensible heat gain

Line 11, Roof heat gain: Instantaneous heat gain through the roof, calculated by CTF coefficients.

From Table 11, the major element of the roof (that layer with the most mass) is the gypsum slab (code number C14). Other elements are the metal deck (A3), rigid insulation (B3), built-up roofing (E3), and gravel surface (E2). Entering Table 12 with these code values, the C14 roof slab designates column 7, and the R-value 11.11 calls for R = 3. From the "mass-in" part of the table and the condition of being "w/o ceiling", the table identifies Roof Group 5 as that whose CTF coefficients will best represent the roof in question.

The CTF coefficients (b, d and $\Sigma_n = 0_{cn}$) are then obtained from Tables 13 and 14, by selecting roof group 5 and adjusting the tabulated b_n and $\Sigma_n = 0\ c_n$ by the U-factor ratio ($U_{example}/U_{table}$) = 0.09 / 0.055 = 1.636.

The adjusted b_n and $\Sigma_{n=0}\ c_n$ are:

$$
\begin{aligned}
b_0 &= 0.00006\ (1.636) &&= 0.00010\\
b_1 &= 0.00256\ (1.636) &&= 0.00419\\
b_2 &= 0.00477\ (1.636) &&= 0.00780\\
b_3 &= 0.00100\ (1.636) &&= 0.00164\\
b_4 &= 0.00002 &&= \text{N/A}\\
b_5 &= 0.00000 &&= \text{N/A}\\
b_6 &= 0.00000 &&= \text{N/A}\\
\sum_{n=0} c_n &= 0.00841\ (1.636) &&= 0.01376
\end{aligned}
$$

The d values (used without modification) are:

$$
\begin{aligned}
d_0 &= 1.00000\\
d_1 &= -1.10395\\
d_2 &= 0.26169\\
d_3 &= -0.00475\\
d_4 &= 0.00002\\
d_5 &= 0.00000\\
d_6 &= 0.00000
\end{aligned}
$$

The heat gain through the roof is calculated by Equation (28), using the sol-air temperature cycle given in line 7 and t_{rc} = 75 °F. The calculations are extended for five daily cycles at which time the daily periodic steady state is effectively reached. The last daily cycle is used as the heat gain through the roof. (*Note*: Three daily cycles are sufficiently accurate in this case, but since calculations do not converge for the more massive wall components before the 93rd hour, all calculations are run to hour 120.)

Lines 12, 13, 14, and 15, Wall heat gain. The instantaneous heat gains through the various walls are calculated by the same approach as that used for the roof. The CTF coefficients selected from Tables 11 and 15 to 19 are:

North and East Exterior Walls
- Dominant element C8, or col. 13 in Integral Mass table (Table 16);
- Interior finish E1;
- R value indicating R of 2 in Table 16;
- Select Wall Group 5 in Tables 18 and 19 for representative factors.

South Wall
- Dominant element C9, or col. 14 in Table 16;
- Exterior layer A2 or A7;
- Interior layer E1 (plywood panel ignored as trivial);
- R value indicating R of 6;
- Select Wall Group 24 for representative factors.

North and West Party Walls
- With no specific data for a 13 in. brick wall, use a layer of 8 in. common brick (C9) and a layer of 4 in. face brick (A2 or A7) as an approximation; thus:
- Dominant element C9, or column 14 in Table 16;
- Exterior layer A2 or A7;
- R value indicating R of 6;
- Select Wall Group 24 in Table 16 for representative factors.

The b_n and $\Sigma_{n=0} c_n$ require multiplication by the U-factor ratio to account for the difference in U-factors. The heat gain is then calculated by Equation (28), using corresponding wall CTF coefficients and sol-air temperatures for south, east, and north walls, and the outside air temperature cycle for north and west party walls.

Lines 16, 17, and 18, Door heat gain: Heat storage of the doors could be assumed negligible, in which case the heat gain would be calculated by Equation (16) as

$$q_{D\theta} = U_D A_D (t_{D\theta} - t_i)$$

where

U_D = 0.19; U-factor of doors (0.18 for interior doors)
A_D = 35; area of a door, ft^2
t_i = 75 °F, inside temperature
$t_{D\theta}$ = outside temperature at door, at time θ

For the door in the north party wall, $t_{D\theta}$ equals outside air temperature. For the doors in east and south walls $t_{D\theta}$ equals the east and south wall sol-air temperatures, respectively.

The foregoing would be a reasonable approach for estimating the minor loads involved. For the purpose of this example however, the relatively brief storage effect of the solid core doors has been considered by use of Equation (28), in accordance with:

Dominant element B7, or column 3 in Table 16;
- Interior finish A6;
- R value indicating R of 8;
- Select Wall Group 1 for representative factors.

Lines 19, 20, and 21, Window heat gain: The air to air heat gain (line 19):

$$q_a = U_w A_w (t_{o\theta} - t_i)$$

where

U_w = 0.81; U-factor of window
A_w = 90; area of windows, ft^2
$t_{o\theta}$ = outside air temperature at time θ

The solar radiation heat gain (lines 20 and 21) through south and north windows:

$$Q_r = A_w \times \text{SC} \times \text{SHGF}_\theta$$

where

SHGF_θ = Solar heat gain factors given in line 5 for south and line 4 for north.
SC = 0.55; shading coefficient for clear window with light colored curtain or blind.

Lines 22 and 23, Heat gain from tungsten and fluorescent lights: For the gain from lighting, Equation (9) is used with a use factor of unity and special allowance factors of 1.20 for fluorescent lamps and of unity for tungsten lamps. Thus:

$q_{el\ tung}$ = 4000 × 1 × 1 × 3.41 = 13,640 Btu/h, and

$q_{el\ fluor}$ = 17,500 × 1 × 1.20 × 3.41 = 71,610 Btu/h

Line 24, Heat gain from people: Sensible heat gain from occupants, for moderately active office work (Table 3):

q_{sp} = (number of people)(sensible heat generated per person)

= 85 × 250 = 21,250 Btu/h

Lines 25 and 26, Sensible heat gain from infiltration and ventilation: As developed in Building Data, the value used for infiltration is 67 cfm, and that for ventilation, 1275 cfm.

Heat gain from infiltration air is part of the space load, while that from ventilation air normally is not. In this example however, since ventilation is delivered directly to the space rather than through the cooling equipment first, its gain is also included as a direct space load.

Note: Had the ventilation air instead been mixed with return air leaving the occupied space and before entering the cooling equipment, only (4) that portion which passed through the cooling coil untreated due to coil inefficiency (or "Bypass Factor", normally 3 to 5% for a chilled water coil of 6 or more rows and close fin spacing up to 15% or more for refrigerant coils in packaged air-conditioning units), and/or (5) that quantity deliberately bypassed around the coil in response to a "face and bypass" or "conventional multizone" space dry-bulb temperature control scheme, would become a part of the space heat gain as such rather than a part of the cooling coil load directly (see 1991 ASHRAE *Handbook—Applications*).

The sensible loads are determined from Equation (25). At 1600 hours for example, when t_o = 94°F and t_i = 75°F, this generates:

q_{si} = 1.1 (Infiltration rate, cfm)$(t_o - t_i)$

= 1.1 × 67(94 − 75) = 1400 Btu/h, and

q_{sv} = 1.1(Ventilation rate, cfm) $(t_o - t_i)$

= 1.1 × 1275(94 − 75) = 26,600 Btu/h

Line 27, Total instantaneous sensible heat gain: The sum of instantaneous heat gain values listed in lines 11 through 26. All such values take into account the delaying effects of insulation and mass of the elements enclosing the conditioned space on the heat that ultimately enters that space, but before considering the thermal inertia of the overall mass and configuration of the building and contents in delaying conversion of radiant heat gain to space cooling load.

(e) Instantaneous latent heat gain

Line 28, People: The latent heat gain due to people, using Table 3 data:

q_{lp} = (number of persons)(latent heat generated by one person)

= 85 × 200 = 17,000 Btu/h during the occupied period.

Lines 29 and 30, Latent heat gain from infiltration and ventilation: The latent loads are determined from Equation (26). At 1600 hours for example, when W_o = 0.0161 and W_s = 0.0093, this generates

q_{li} = 4840(Infiltration rate, cfm) $(W_o - W_s)$

= 4840 × 67(0.0161 − 0.0093) = 2,205 Btu/h, and

q_{lv} = 4840(Ventilation rate, cfm) $(W_o - W_s)$

= 4840 × 1275(0.0161 − 0.0093) = 41,963 Btu/h

Line 31, Total latent heat gain: The total latent heat gain, *i.e.*, the sum of lines 28, 29, and 30.

Line 32, Sum of instantaneous sensible and latent heat gain: The sum of heat gain values from lines 27 and 31.

(f) Cooling load from convective sensible heat gain components

Lines 33 through 38: Direct inclusion of the convective portions of instantaneous heat gain components listed in lines 19, 25, and 26, and 20%, 50%, and 67% of lines 22, 23, and 24 respectively. These room sensible heat gain components (*i.e.*, loads due to air-to-air heat gain through windows, tungsten lights, fluorescent lights, infiltration, ventilation, and heat gain due to people by convection, all appear as cooling load without delay. Percentages of heat gain considered corrective are listed in Table 3 and Table 44 under the section describing TETD/TA procedures. Selection of 33% of sensible gain for people as radiant is an approximation for purposes of this example.

(g) Cooling load from radiant sensible heat gain components

Lines 39 through 41: Heat gain data from lights and people (lines 22 through 24) are processed by Equation (31) using RTF coefficients from Tables 24 and 25:

From Table 24, assuming "medium" mass of building and contents, the 75 lb/ft² specific mass classification can be considered representative. Assuming a conventional supply diffuser and non-plenum return air arrangement with inside surface coefficient h = 0.6 Btu/(h · ft² · °F), or "medium" type indicates a w_1 value of −0.94; except with an uncarpeted floor the next w_1 value down the column is used, or 0.93.

From the lower part of Table 25, assuming ordinary furnishings, no carpet, medium air circulation, supply and return below ceiling, and unvented light fixtures, the v_0 value for lighting is 0.55 and v_1 = 1 + (−0.93) −0.55 = −0.48.

For people, the upper part of Table 25 calls for a v_0 of 1.0 and v_1 of 0 to be applied to convective heat gain (instantaneous conversion to cooling load), and for radiant heat gain a v_0 of 0.197 and v_1 = 1 + (−0.93) −0.197 = −0.127.

Note that the TFM treatment of lighting heat gain is "generic," without individual regard to the differences in radiant/convective percentages of heat gain from incandescent, fluorescent, or other type lamps, and the RTF coefficients are applied to the combined sensible heat gain values. For the purposes of this example, to facilitate comparison with other calculation methods, the values in lines 39 and 40 represent the hourly results of Equation (31) less the amounts of instantaneous cooling load included and indicated on lines 34 and 35.

(h) Cooling load from convective and radiant sensible heat gain components

Lines 42 through 51: Elements of instantaneous heat gain from solar radiation through windows, walls, doors and roof, *i.e.*, sum of values listed in lines 11 to 21, delayed in being felt as cooling load by the space. Data listed in lines 42 through 51 are the results of applying Equation (31) and appropriate RTF coefficients to the heat gain values from lines 11 through 21, without separately considering radiant or convective components. RTF coefficients are taken from Tables 24 and 25 in the manner above described for lighting loads, producing:

From Table 24, w = −0.93 in all cases.

From the upper part of Table 25, all cases fall within the second category described, which for "medium" building and contents mass indicates v_0 = 0.681 and v_1 = 1 + (−0.93) − 0.681 = −0.611.

The heat gain by solar radiation transmitted through windows is included with heat gain through walls and roof because the venetian blind intercepts solar radiation and releases it to the room in a similar way as the heat gain through walls and roof.

Note: If the glass had no internal shading, the solar radiation through windows would have to be treated by a different set of RTF coefficients to account otherwise for thermal storage (see Tables 24 and 25). Translucent draperies fall somewhere between these limits, with assumed linear relationship in the absence of specific research on the subject (see Chapter 27).

Line 52, Total room sensible cooling load: Total sensible cooling load felt by the room, and the design sensible load used as the basis for sizing cooling equipment. This total load is the sum of the values listed in lines 33 through 51. The tiny difference between the 24 hour total of 2,042,698 Btu/h on line 52 and the sum of the 24 hour totals for lines 11 through 26 reflects rounding of values during intermediate computation.

2. **Latent Cooling Load**

Line 31—The sum of lines 28, 29, and 30: Total Latent Heat Gain is also the Total Latent Cooling Load, as all components occur instantaneously.

3. **Total cooling load**

Line 53—The sum of lines 52 and 31: Note that the Total Cooling Load for this example problem is the theoretical total for the conditions as defined, and may or may not represent the actual total cooling load imposed upon a system of cooling equipment. An appropriate psychrometric analysis should be performed of supply air, space air, return air, and mixed air (where ventilation air is mixed with return air en route back to the cooling equipment), considering the type of cooling equipment and characteristics of the preferred control scheme. Only an analysis of this

type can verify that the design will meet the requirements, and determine whether the actual sensible, latent, and total cooling loads are greater or less than the theoretical values calculated (see 1992 ASHRAE *Handbook—Systems and Applications*).

4. **Capacity of system to maintain conditions**
   (a) *Fixed temperature*: 75 °F indoor temperature, 24 hour "on" period: The basic calculation procedure assumes a fixed indoor temperature, in this case 75 °F; thus the results tabulated in lines 1 through 42 are for this condition.
   (b) 2 °F throttling range: Indoor temperature in the range 75 to 77 °F, 24 hour "on" period.
   (c) 4 °F throttling range: Indoor temperature in the range 75 to 79 °F, 24 hour "on" period.
   (d) 2 °F throttling range: Indoor temperature in the range 75 to 77 °F, 10 hour "on" period, 0800 through 1700.
   (e) 4 °F throttling range: Indoor temperature in the range 75 to 79 °F, 12 hour "on" period, 0600 through 1700.

Line 54, Sensible cooling load with loss to surroundings: To be consistent with the concept of heat extraction and resultant space temperatures, certain cooling load elements must be modified to account for heat loss to surroundings. The multiplier $F_c = 0.94362$ was calculated by the process noted for each of the envelope element areas times the respective U-factors, dividing the sum by the building perimeter to develop K_θ, and generating F_c by Equations (37) and (38); then using F_c to reduce the appropriate load elements. The sum of all modified and unmodified load elements is listed on line 53 as the basis for the various heat extraction/space temperature evaluations.

Lines 55 through 62, Air temperatures and heat extraction rates: Heat extraction and indoor air temperatures are based on the normalized SATF coefficients for medium weight construction listed in Table 26 and calculated by use of Equations (39) through (43) in the procedure previously described. The SATF coefficients for this example are thus for hour θ (0800 – 1700):

$$g_{0\theta} = g_0^* (\text{Floor area}) + p_0 [K_\theta (\text{Perimeter length}) + 1.1(\text{Ventilation and Infiltration})]$$
$$= (1.81 \times 4000) + 1.0 [(4.86 \times 260) + 1.1(1275 + 67)]$$
$$= 7240 + (1263.4 + 1476.2) = 9980$$

$$g_{1\theta} = g_1^* (\text{Floor area}) + p_1 [K_\theta (\text{perimeter length}) + 1.1(\text{Ventilation and Infiltration})]$$
$$= (-1.89 \times 4000)(-0.87)[(4.86 \times 260) + 1.1 (1275 + 67)]$$
$$= -7560 - 0.87 (1263.4 + 1476.2) = -9944$$

$$g_{2\theta} = g_2^* (\text{Floor area}) = 0.08 \times 4000 = 320$$

$$p_0 = 1.0000$$

$$p_1 = -0.87$$

The heat extraction rates and room air temperatures listed in lines 55 through 62 are calculated using these SATF coefficients, the modified total sensible cooling load values listed in line 54, and the specified throttling ranges and "on" and "off" periods.

The maximum sensible heat extraction capacity required to maintain the space temperature at a constant 75 °F can be taken as the design peak value on line 52, or 149,470 Btu/h at 1600 hours.

The maximum sensible heat extraction capacity required to maintain interior temperature within a 75 to 77 °F range is 145,693 Btu/h (hour 1600, line 54), and within a 75 to 79 °F range is 139,602 Btu/h (hour 1700, line 56), assuming continuous operation of cooling equipment.

Comparable maintenance of space temperature ranges during equipment operation hours (limited to 10 hours and 12 hours respectively) requires heat extraction rates of 146,600 Btu/h (hours 0800 to 1700, line 60) and 146,600 Btu/h (hours 1200 to 1700, line 62) respectively. Here ER_{max} needs to be increased if the heat accumulated overnight is to be overcome; but the total daily heat extraction still will be significantly less than for continuous operation.

5. **Heating Load**

Lines 11 through 19, Heat loss by conduction: The heat loss column lists for each of the building envelope components a single value representing the product of exposed area, U-factor, and the temperature difference between inside design dry bulb and outside design dry bulb temperatures for winter conditions, in an adaptive use of Equation (8). Often, a lower inside design dry bulb temperature is selected for winter conditions than for summer, and, where appropriate, the U-factors are adjusted to reflect different average exterior wind velocities. For this example, the same inside temperatures and U-factors are used year-round.

These results are design heat loss values, which are used to establish a "design heating load" with which to design heating systems and to select properly sized equipment components. When the load calculation is used to analyze energy performance, hourly calculations of heat loss that reflect the profile of outside weather conditions must be run (see Chapter 28).

Lines 20 through 21, Solar heat gain: For *design* heating loss calculations, offsetting values of solar heat gain are routinely ignored at night or during periods of extended cloud cover, and thus not consistently available to assist the installed heating equipment. Designers must, however, consider the higher solar heat gain values that occur during winter months due to low solar angles that often cause peak cooling loads through large areas of exposed glass. Hourly calculations are required for energy use evaluation.

Lines 22, 23, and 24, Internal heat gains: Like solar heat gain, the heat from internal sources requires year-round cooling for completely interior spaces and contributes to unseasonable cooling requirements in conjunction with glass loads on sunny days. For conventional heating load purposes, however, these loads are normally ignored because of their uncertainty during all hours of need and since their full effect does not occur until some number of hours after occupancy begins during intermittent schedules. Heat gain values in this example are given as "negative heat loss" figures, and not routinely included in design heating load summaries.

Lines 25 and 26, Infiltration and ventilation: Values listed for these variables are calculated on the basis of a single "worst case" hour under winter design temperature conditions, adapting Equation (25) in a similar manner to that noted for conduction heat losses.

Humidification: For this example, the issue of maintaining interior humidity levels during winter months has been ignored. While this represents routine practice for most applications in latitudes 35 °N and lower, humidity levels are of major concern in colder climates. (see Chapter 21).

Line 52, Total sensible heat loss: The sum of heat loss values from lines 11 through 19, 25, and 26, and which conventionally represents the design heating load for the building. Internal heat gain figure from lines 22, 23, and 24 are not included in this total.

Line 53, Net sensible heat loss, considering internal heat gains: The heat loss summary value if internal heat gains were to be included in the total, illustrated here only to emphasize the potential significance of such elements and the importance of providing an appropriate means of temperature control for differently affected building areas.

CLTD/SCL/CLF CALCULATION PROCEDURE

To calculate a space cooling load using the CLTD/SCL/CLF convention, the same general procedures outlined for the TFM relative to data assembly and use of data apply. Similarly, the basic heat gain calculation concepts of solar radiation, total heat gain through exterior walls and roofs, heat gain through interior surfaces, and heat gain through infiltration and ventilation are handled in an identical manner.

The CLTD/SCL/CLF method is a one-step, hand calculation procedure, based on the transfer function method (TFM). It may be used to approximate the cooling load corresponding to the first three modes of heat gain (conductive heat gain through surfaces such as windows, walls, and roofs; solar heat gain through fenestrations; and internal heat gain from lights, people, and equipment) and the cooling load from infiltration and ventilation. The acronyms are defined as follows:

CLTD—Cooling Load Temperature Difference
SCL—Solar Cooling Load
CLF—Cooling Load Factor

The following sections give details of how the CLTD/SCL/CLF technique relates to and differs from the TFM. The sources of the space cooling load, forms of equations to use in the calculations, appropriate references, tables, are summarized in Table 29.

SYNTHESIS OF HEAT GAIN AND COOLING LOAD CONVERSION PROCEDURES

Exterior Roofs and Walls

This method was developed by using the TFM to compute one-dimensional transient heat flow through various sunlit roofs and walls. Heat gain was converted to cooling load using the room transfer functions for rooms with light, medium, and heavy thermal characteristics. Variations in the results due to such varying room constructions and other influencing parameters discussed in the TFM description are so large that only one set of factors is presented here for illustration. All calculations for data tabulated were based on the sol-air temperatures in Table 1. The inside air temperature was assumed to be constant at 78 °F (cooling system in operation 24 h/day, seven days a week). The mass of building and contents was "light to medium". For application of CLTD/SCL/CLF techniques, refer to the *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992).

Basic CLTD cooling load for exterior surfaces. The results were generalized to some extent by dividing the cooling load by the U-factor for each roof or wall and are in units of total equivalent cooling load temperature difference (CLTD). This establishes the basic cooling load equation for exterior surfaces as:

$$q = UA\,(\text{CLTD}) \tag{44}$$

where

q = cooling load, Btu/h
U = coefficient of heat transfer, Btu/(h·ft²·°F)

Table 29 Procedure for Calculating Space Design Cooling Load by CLTD/SCL/CLF Method

External Cooling Load

Roofs, walls, and conduction through glass

$$q = UA\,(\text{CLTD}) \tag{44), (55}$$

U = design heat transfer coefficient for roof or wall from Chapter 22, Table 4; or for glass, Table 5, Chapter 27
A = area of roof, wall, or glass, calculated from building plans
CLTD = cooling load temperature difference, roof, wall, or glass

Solar load through glass

$$q = A\,(\text{SC})(\text{SCL}) \tag{46}$$

SC = shading coefficient: Chapter 27
SCL = solar cooling load factor with No Interior Shade, or With Shade Table 36.

Cooling load from partitions, ceilings, floors

$$q = UA\,(t_b - t_{rc}) \tag{8}$$

U = design heat transfer coefficient for partition, ceiling, or floor, from Chapter 22, Table 4
A = area of partition, ceiling, or floor, calculated from building plans
t_b = temperature in adjacent space
t_{rc} = inside design temperature (constant) in conditioned space

Internal Cooling Load

People

$$q_{sensible} = N(\text{Sensible heat gain})\,\text{CLF} \tag{47}$$

$$q_{latent} = N(\text{Latent heat gain}) \tag{48}$$

N = number of people in space, from best available source. Sensible and latent heat gain from occupancy—Table 3, or Chapter 8; adjust as required
CLF = cooling load factor, by hour of occupancy, Table 37

Note: CLF = 1.0 with high density or 24-h occupancy and/or if cooling off at night or during weekends.

Lights

$$q_{el} = 3.41\,W F_{ul} F_{sa}\,(\text{CLF}) \tag{9), (49}$$

W = watts input from electrical plans or lighting fixture data
F_{ul} = lighting use factor, from Section I, as appropriate
F_{sa} = special allowance factor, from Section I, as appropriate
CLF = cooling load factor, by hour of occupancy, Table 38

Note: CLF = 1.0 with 24-h light usage and/or if cooling off at night or during weekends.

Power

$$q_p = 2545\,PE_F\,\text{CLF} \tag{15), (16), (17), (50}$$

P = horsepower rating from electrical plans or manufacturer's data
E_F = efficiency factors and arrangements to suit circumstances
CLF = cooling load factor, by hour of occupancy, Table 37

Note: CLF = 1.0 with 24-h power operation and/or if cooling off at night or during weekends.

Appliances

$$q_{sensible} = q_{is} F_{ua} F_{ra}\,(\text{CLF}) \tag{18), (50}$$

or

$$q_{sensible} = (q_{is} F_{ua} F_{ra}\,\text{CLF})/F_{fl} \tag{20), (50}$$

$$q_{latent} = q_{il} F_{ua} \tag{22}$$

q_{is}, q_{il} = sensible and latent heat gain from appliances—Tables 5 through 9, or manufacturer's data
F_{ua}, F_{ra}, F_{fl} = use factors, radiation factors, flue loss factors from the General Principles section
CLF = cooling load factor, by scheduled hours and hooded or not; Tables 37 and 39

Note 1: CLF = 1.0 with 24-h appliance operation and/or if cooling off at night or during weekends.
Note 2: Set latent load = 0 if appliance under exhaust hood.

Ventilation and Infiltration Air

$$q_{sensible} = 1.10\,Q\,(t_o - t_i) \tag{25}$$

$$q_{latent} = 4840\,Q\,(W_o - W_i) \tag{27}$$

$$q_{total} = 4.5\,Q\,(H_o - H_i) \tag{23}$$

Q = ventilation cfm from ASHRAE *Standard* 62; infiltration from Chapter 23
t_o, t_i = outside, inside air temperature, °F
W_o, W_i = outside, inside air humidity ratio, lb water/lb dry air
H_o, H_i = outside, inside air enthalpy, Btu/lb dry air

A = area of surface, ft²
CLTD = cooling load temperature difference

In developing the method, it was assumed that the heat flow through a similar roof or wall (similar in thermal mass as well as U-factor) can be obtained by multiplying the total CLTDs listed in Tables 30 or 32 by the U-factor of the roof or wall at hand, respectively. The errors introduced by this approach depend on the extent of the differences between the construction in question (components, size, configuration, and general mass of building and contents) and the one used for calculating the CLTDs.

The sol-air temperature value depends on outdoor air temperature as well as the intensity of solar radiation. Consequently, a change in either outdoor air temperature or geographic location changes the sol-air temperature. The CLTD values in the tables were computed for an indoor air temperature of 78 °F, an outdoor maximum temperature of 95 °F, and an outdoor mean temperature of 85 °F, with an outdoor daily range of 21 °F and a solar radiation variation typical of 40 °N latitude on July 21.

The notes associated with Tables 30 and 32 provide descriptions of the conditions under which the CLTD values were calculated. While variations in exterior color and/or outside and inside surface film resistances do have some effect, their impact on roofs or walls of contemporary construction is relatively minor and can be ignored with data that is already normalized for convenience. Variations in inside space temperature or the mean outdoor temperature are of much more significance, and the means of appropriate adjustment are thus outlined. Additional guidance for specific application may be found along with tables for a broad range of latitudes in the *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992).

Space Cooling Load from Fenestration

The basic principles of calculating heat gain from conduction and solar radiation through fenestration are as previously discussed for the TFM.

CLTD Cooling load from conduction. For conduction heat gain, the overall heat transfer coefficient accounts for the heat transfer processes of (1) convection and long-wave radiation exchange outside and inside the conditioned space, and (2) conduction through the fenestration material. To calculate cooling load for this component, the conduction heat gain is treated in a manner similar to that through walls and roofs. The RTF coefficients used to convert the heat gain to cooling load are thus the same as those for walls and roofs. The resulting CLTDs are given in Table 32, again presenting only a single set of factors for all room construction types, neglecting the effects of mass and latitude due to the generally low density and the small magnitude of these components. The CLTDs from Table 32 can also be used for doors with reasonable accuracy. The cooling load from conduction and convection heat gain is calculated by:

$$q_{cond} = UA(\text{CLTD}) \tag{45}$$

where A is the net glass area of the fenestration in square feet. [Note that the equation is identical to Equation (44).]

Solar heat gain. The basic principles of evaluating heat gain from transmitted and absorbed solar energy through fenestration, including the primary terms SHGF and SC, are the same for the CLTD/CLF procedure as previously described for the TFM.

Previous ASHRAE Handbooks tabulated values of maximum solar heat gain factors for sunlit or externally shaded double-strength sheet glass, used as the heat gain input for calculating cooling load factors (CLFs), employing appropriate RTF coefficients as in the TFM discussion. This process, however, introduced new variables into the calculations: (1) the presence or absence of interior shading devices, which is pivotal, and (2) the construction, furnishings, floor coverings, and relative amounts of fenestration, which are critical when interior shading is absent. Results obtained with this method do not recognize the significant variation of solar cooling load profiles due to different latitudes, months, and other factors. A new term, solar cooling load (SCL), is introduced to more closely approximate cooling loads due to solar radiation transmitted through fenestration.

Cooling load caused by solar radiation through fenestration is calculated by:

$$q_{rad} = A(\text{SC})(\text{SCL}) \tag{46}$$

where

q_{rad} = cooling load caused by solar radiation, Btu/h
A = net glass area of fenestration, ft²
SC = shading coefficient, for combination of fenestration and shading device, obtained from Chapter 27
SCL = solar cooling load, Btu/(h·ft²), from Table 36

Total cooling load from fenestration. The total cooling load due to fenestration is the sum of the conductive and radiant components q_{cond} and q_{rad}.

Zone influencing parameters. For purposes of estimating a cooling load, a zone is a particular combination of conditions defining the space under consideration, and which govern the absorption and release of radiant energy. The SCL for a particular zone depends on latitude, direction, nature, and quantity of enclosing surfaces, as well as various internal parameters that influence the SHGF for each glass exposure in that zone.

To determine the most appropriate SCL table for a zone, refer to Tables 35A and 35B, where zone types (A, B, C, or D) are given as functions of some of the more dominant of the 16 zone parameters defined in the TFM discussion. The SCLs for sunlit glass at 40 °N latitude and one month, July, are tabulated in Table 36 for each zone type. SCLs for externally shaded glass may be taken from these tables as those for North exposure, although with some loss of accuracy at latitudes lower than 24 °N. Interpolation between latitudes can be performed with some loss of accuracy. The *Cooling and Heating Load Calculation Manual* (McQuiston and Spitler 1992) includes additional data for multistory buildings and for other latitudes, months, and zone types.

Shading Coefficient

Interior shading. The cooling load from solar radiation must be analyzed for one of two cases: (1) presence of interior shading or (2) absence of interior shading. Blinds (venetian or roller shades) or drapes absorb the solar energy before it can strike the floor or other interior surfaces of the space, which leads to a rapid response in the cooling load due to the low mass of the shading device.

When interior shading is absent, the solar energy is absorbed by the more massive elements of the space, which results in increased delay in such heat gain being converted to cooling load. Many variables, of which the more important are the presence or absence of carpet on the floor, mass of the floor and other surfaces, mass of the contents of the space, amount of glass in the exposed surfaces, presence or absence of a ceiling, the relative size of the space, etc., have influence on this phenomenon.

The composite effect of the various forms of interior shading on solar radiation from glass, relative to unshaded clear double-strength glass, is represented by a shading coefficient (SC) or decimal multiplier, tabulated in Chapter 27 for a wide variety of conditions.

Exterior shading. Where glass is shaded by exterior means of a permanent nature, the hourly mitigating effect of such shading may be estimated by separate evaluations of shaded areas relative to unshaded areas for each situation as previously noted.

Note 1. Direct application of data
- Dark surface
- Indoor temperature of 78°F
- Outdoor maximum temperature of 95°F with mean temperature of 85°F and daily range of 21°F
- Solar radiation typical of clear day on 21st day of month
- Outside surface film resistance of 0.333 (h · ft² · °F)/Btu
- With or without suspended ceiling but no ceiling plenum air return systems
- Inside surface resistance of 0.685 (h · ft² · °F)/Btu

Note 2. Adjustments to table data
- Design temperatures : Corr. CLTD = CLTD + (78 − t_r) + (t_m − 85)

  where

  t_r = inside temperature and t_m = mean outdoor temperature

  t_m = maximum outdoor temperature − (daily range)/2
- No adjustment recommended for color
- No adjustment recommended for ventilation of air space above a ceiling

Note 1. Direct application of data
- Dark surface
- Indoor temperature of 78°F
- Outdoor maximum temperature of 95°F with mean temperature of 85°F and daily range of 21°F
- Solar radiation typical of clear day on 21st day of month
- Outside surface film resistance of 0.333 (h · ft^2 · °F)/Btu
- Inside surface resistance of 0.685 (h · ft^2 · °F)/Btu

Note 2. Adjustments to table data
- Design temperatures

$$\text{Corr. CLTD} = \text{CLTD} + (78 - t_r) + (t_m - 85)$$

where
t_r = inside temperature and
t_m = maximum outdoor temperature − (daily range)/2
- No adjustment recommended for color

*Denotes a wall that is not possible with the chosen set of parameters.
**See Table 11 for definition of Code letters.

Example 7. Cooling load from south and west glass. Determine the cooling load caused by glass on the south and west walls of a building at 1200, 1400, and 1600 h in July. The building is located at 40°N latitude with outside design conditions of 90°F dry-bulb temperature and a 20°F daily range. The inside design dry bulb temperature is 78°F. Assume the room configuration includes two exposed walls, vinyl floor covering, and gypsum partitions, and that the building is a single story. The south glass is insulating type (0.25 in. air space) with an area of 100 ft² and no interior shading. The west glass is 7/32 in. single grey-tinted glass with an area of 100 ft² and with light-colored venetian blinds.

Solution: By the room configuration described and with inside shading for half the exposed glass area, Table 35B indicates the SCL factors should be selected for a Zone C condition.

Data required for the calculation are as follows:

Variable		South Glass	West Glass
U, Btu/(h·ft²·°F)*		0.61	0.81
Area A, ft²		100	100
SC (Chapter 27)		0.82	0.53
SCL (Table 36, Zone C)	1200	79	37
	1400	80	98
	1600	40	153

*U-factors based on previous edition of this Handbook. See Table 5, Chapter 27 for current values.

Table 34 Cooling Load Temperature Differences (CLTD) for Conduction through Glass

Solar Time, h	CLTD, °F	Solar Time, h	CLTD, °F
0100	1	1300	12
0200	0	1400	13
0300	−1	1500	14
0400	−2	1600	14
0500	−2	1700	13
0600	−2	1800	12
0700	−2	1900	10
0800	0	2000	8
0900	2	2100	6
1000	4	2200	4
1100	7	2300	3
1200	9	2400	2

Corrections: The values in the table were calculated for an inside temperature of 78°F and an outdoor maximum temperature of 95°F with an outdoor daily range of 21°F. The table remains approximately correct for other outdoor maximums 93 to 102°F and other outdoor daily ranges 16 to 34°F, provided the outdoor daily average temperature remains approximately 85°F. If the room air temperature is different from 78°F and/or the outdoor daily average temperature is different from 85°F, see note 2, Table 32.

The conduction heat gain component of cooling load by Equation (45) is:

Time	CLTD (Table 34)	CLTD Correction	South Glass, Btu/h	West Glass, Btu/h
1200	9	4	244	324
1400	13	8	488	648
1600	14	9	549	729

The correction factor applied to the above CLTDs was −5°F, computed from the notes of Table 34. Heat gain values are rounded.

The solar heat gain component of cooling load by Equation (46) is:

Time	South Glass SC	South Glass SCL	SHG, Btu/h	West Glass SC	West Glass SCL	SHG, Btu/h
1200	0.82	79	6478	0.53	37	1961
1400	0.82	70	5740	0.53	98	5194
1600	0.82	40	3280	0.53	153	8109

	1 in. Wood	N/A	b	C	B

[a]A total of 14 zone parameters is fully defined in Table 20. Those not shown in this table were selected to achieve an error band of approximately 10%.
[b]The effect of inside shade is negligible in this case.

Table 35B Zone Types for Use with SCL and CLF Tables, Single-Story Building

Zone Parameters[a]				Zone Type			Error Band	
No. Walls	Floor Covering	Partition Type	Inside Shade	Glass Solar	People and Equipment	Lights	Plus	Minus
1 or 2	Carpet	Gypsum	b	A	B	B	9	2

4	Vinyl	Gypsum	Half to None	C	C	C	19	−1

[a]A total of 14 zone parameters is fully defined in Table 20. Those not shown in this table were selected to achieve the minimum error band shown in the righthand column for Solar Cooling Load (SCL). The error band for Lights and People and Equipment is approximately 10%.

[b]The effect of inside shade is negligible in this case.

Notes:
1. Values are in Btu/h · ft^2.
2. Apply data directly to standard double strength glass with no inside shade.
3. Data applies to 21st day of July.
4. For other types of glass and internal shade, use shading coefficients as multiplier. See text. For externally shaded glass, use north orientation. See text.

The total cooling load due to heat gain through the glass is, therefore:

Time	South Glass, Btu/h	West Glass, Btu/h
1200	6722	2285
1400	6198	5842
1600	3829	8838

HEAT SOURCES WITHIN CONDITIONED SPACE

People

The basic principles of evaluating heat gain and moisture generation from people are the same as those previously described for the TFM. Latent heat gains are considered instantaneous cooling loads.

The total sensible heat gain from people is not converted directly to cooling load. The radiant portion is first absorbed by the surroundings (floor, ceiling, partitions, furniture) then convected to the space at a later time, depending on the thermal characteristics of the room. The radiant portion of the sensible heat gain from people varies widely depending on the circumstances, as indicated by Table 3 and in more detail by Chapter 8. A 70% value was used to generate CLFs for Table 37, which considers the storage effect on this radiant load in its results, plus the 30% convective portion. The instantaneous sensible cooling load is thus:

$$q_s = N(\mathrm{SHG}_p)(\mathrm{CLF}_p) \tag{47}$$

and the latent cooling load is:

$$q_l = N(\mathrm{LHG}_p) \tag{48}$$

where

q_s = sensible cooling load due to people
N = number of people
SHG_p = sensible heat gain per person (Table 3)

Table 37 Cooling Load Factors for People and Unhooded Equipment

Hours in Space	Number of Hours after Entry into Space or Equipment Turned On: 1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24

Note: See Table 35 for zone type. Data based on a radiative/convective fraction of 0.70/0.30.

CLF_p = cooling load factor for people (Table 37)
q_l = latent cooling load due to people
LHG_p = latent heat gain per person (Table 3)

The CLF for people load is a function of the time such people spend in the conditioned space and the time elapsed since first entering. As defined for estimating cooling load from fenestration, the space under consideration is categorized as a zone, identified in Table 35. The appropriate CLF is selected from Table 37 by zone type, occupancy period, and number of hours after entry.

CLF Usage exceptions. If the space temperature is not maintained constant during the 24-h period, for example, if the cooling system is shut down during the night (night shutdown), a "pulldown load" results because a major part of the stored sensible heat in the structure has not been removed, thus reappearing as cooling load when the system is started the next day. In this case, a CLF of 1.0 should be used.

When there is a *high occupant density*, as in theaters and auditoriums, the quantity of radiation to the walls and room furnishings is proportionately reduced. In these situations, a CLF of 1.0 should also be used.

Example 8. Cooling load from occupants. Estimate the cooling load in a building at 1200, 1400, and 1600 h from four moderately active people occupying an office from 0900 to 1700 h. The office temperature is 78 °F, and the cooling system operates continuously. Assume the conditions of the space as applied to Table 33A; define it as Type D.

Solution: The sensible cooling load is calculated by Equation (47), and the latent cooling load is calculated by Equation (48). The period of occupancy is 8 h. Therefore,

Time	No. of People	Hours in Space	Hours after Entry	Btu/h, each (Table 3) Sen.	Lat.	CLF_p (Table 37) Zone D	Cooling Load Sen., Btu/h	Lat., Btu/h
1200	4	8	3	255	255	0.74	755	1020
1400	4	8	5	255	255	0.80	816	1020
1600	4	8	7	255	255	0.85	867	1020

Lighting

As discussed for the TFM, the cooling load from lighting does not immediately reflect the full energy output of the lights. Kimura and Stephenson (1968), Mitalas and Kimura (1971), and Mitalas (1973) indicated the effect on cooling load of light fixture type, type of air supply and return, space furnishings, and the thermal characteristics of the space. The effect of these influencing parameters have been incorporated in the *Heating and Cooling Load Calculation Manual* (McQuiston and Spitler 1992) into the CLF values for lighting listed in Table 38, and for which selection zones are identified as appropriate by Tables 35. At any time, the space cooling load from lighting can be estimated as:

$$q_{el} = HG_{el}(CLF_{el}) \quad (49)$$

where

q_{el} = cooling load from lighting, Btu/h
HG_{el} = heat gain from lighting, Btu/h, as $WF_{ul}F_{sa}$ [Equation (9)]
W = total lamp watts
F_{ul} = lighting use factor
F_{sa} = lighting special allowance factor
CLF_{el} = lighting cooling load factor (Table 38)

CLF_{el} data in Table 38 are based on the assumptions that (1) the conditioned space temperature is continuously maintained at a constant value, and (2) the cooling load and power input to the lights eventually become equal if the lights are on for long enough.

Operational exceptions. If the cooling system operates only during occupied hours, the CLF_{el} should be considered 1.0 in lieu of the Table 38 values. Where one portion of the lights serving the space is on one schedule of operation and another portion is on a different schedule, each should be treated separately. Where lights are left on for 24 h a day, the CLF_{el} is 1.0.

Example 9. Cooling load from lighting. Estimate the cooling load in a building at 1200, 1400, and 1600 h from recessed fluorescent lights, turned on at 0800 h and turned off at 1800 h. Lamp wattage is 800 W. The use

Note: See Table 35 for zone type. Data based on a radiative/convective fraction of 0.59/0.41.

factor is 1.0, and the special allowance factor is 1.25. The room is an interior type in a one-story building, has tile flooring over a 3-in. concrete floor, and a suspended ceiling. The cooling system runs 24 h/day, including weekends.

Solution: From Table 35B, the room is categorized as Type C for lighting load purposes. Therefore,

Time	Hours in Space	Hours after Entry	Lamp Watts	Heat Gain, Btu/h [Eq. (15)]	CLF_{el} (Table 38) Zone C	Cooling Load, Btu/h [Eq. (42)]
1200	8	3	800	3410	0.85	2489
1400	8	5	800	3410	0.89	2660
1600	8	7	800	3410	0.91	2796

Power and Appliances

Heat gain of power-driven equipment can be estimated by means of Equations (15), (16), or (17) as applicable, or taken directly from Tables 4 and/or 5.

Equations (18) through (21) can be used to estimate heat gain values under various circumstances, and Tables 6 through 9 provide representative data for direct use or as input to the equations. Latent heat gain from appliances is considered instantaneous cooling load and is calculated by Equation (22).

The radiant component of sensible heat gain from power-driven equipment or appliances is delayed in becoming cooling load in the same manner as that of other load categories already discussed. For power-driven equipment, the CLF values tabulated for unhooded equipment (Table 37) are considered appropriate. Tables 37 and 39 tabulate cooling load factors (CLF_a) for appliances. Multiplying the sensible portion of heat gain by the appropriate CLF_a will produce the following approximate cooling load values:

$$q = \text{SHG}(\text{CLF}) \tag{50}$$

Example 10. Appliance cooling load. Determine the cooling load in a building at 1200, 1400, and 1600 h caused by an electric coffee brewer with one brewer and one warmer. The brewer operates continuously from 0900 to 1500 h and does not have an exhaust hood. The room is a "midfloor" type in a multistory building, has carpet over a 3-in. concrete floor, and a suspended ceiling. The cooling system runs 24 h/day, including weekends.

Solution: From Table 7, q_s and q_l for an unhooded, two-burner coffee brewer is 3750 and 1910 Btu/h, respectively (thus 1875 and 955 each burner), and for a coffee heater (per warming burner) is 230 and 110 Btu/h, respectively. The brewer is on for 6 h, and 1200 h is 3 h after the brewer is turned on. From Table 35B, the room is categorized as Type D for equipment load purposes. Therefore,

Table 39 Cooling Load Factors for Hooded Equipment

Total Space Cooling Load

The estimated total space cooling load for a given application is determined by summing the individual components for each hour of interest.

EXAMPLE COOLING LOAD CALCULATION USING CLTD/CLF METHOD

Example 11. For this example, the one-story commercial building in Example 6 will be the basis for calculating a cooling load by the CLTD/SCL/CLF method. Refer to Example 6 for the statement of conditions.

Find (for stated design conditions):

1. Sensible cooling load
2. Latent cooling load
3. Total cooling load

Solution: By inspection, the cooling load from the roof can be expected to be the variable making the greatest contribution to the overall cooling load for the building. Therefore, the time of maximum cooling load occurrence will probably be close to the time of maximum CLTD for the roof. The maximum cooling load for the building as a whole can be expected to occur in one of the summer months—June, July, or August. From Table 31, a "mass inside" roof with no ceiling and an R-factor of 11.1 is classified as Type 4. From Table 30, the CLTD for Roof No. 4 at 40 °N latitude has a maximum tabulated value of 78 °F at 1800 h, but is only somewhat less (73) at 1600 h.

South-facing glass can also be expected to wield considerable influence on the cooling load for this particular building. From Table 35A, a one-story building with three exposed walls, uncarpeted floor, masonry partitions, and fully inside-shaded windows is classified B for solar loads, and C for loads from people, equipment, or lights. Cross-checking the variation of SCLs for glass facing south, in Table 36, the maximum cooling load from these windows would be only slightly more at noon or 1300 h than at 1400 for 40 °N latitude. Sometime in the early afternoon seems obvious, but it is necessary to make a quick estimate to establish the peak load hour:

Roof [Equation (44)]

$$U = 0.09 \text{ Btu/(h} \cdot \text{ft}^2 \cdot \text{°F)} \quad \text{Area} = 4000 \text{ ft}^2$$

Time	1300	1400	1500	1600	1700
CLTD	42	54	65	73	77
C_1	3	3	3	3	
C_2	−1	−1	−1	−1	−1
Corr. CLTD	44	56	67	75	79
Btu/h	15840	20160	24120	27000	28440

$C_1 = (78 - 75)$ = indoor design temperature correction

$C_2 = (94 + 74)/2 - 85$ = daily average temperature correction

South Glass, Solar [Equation (46)]:

$$SC = 0.55 \quad \text{Area} = 60 \text{ ft}^2$$

Time		1300	1400	1500	1600	1700
SCL at 40°, Btu/h	=	87 2871	79 2607	63 2079	46 1518	37 1221
Roof and south glass, Btu/h	=	18711	22767	26199	28518	29661

Evaluation of the foregoing indicates that 1600 h will be the probable hour of maximum cooling load for this building, considering that although the roof and south glass loads increase another 1143 Btu/h for 1700 h, the trend has slowed and most other load components of significance can be expected to be leveling off or moving toward lower values at that time. In some cases there would be no such clear cut indication, and it would be necessary to estimate the total load for a number of hours, including the potential impact of other significant variables which could exert a determining influence at a different time (such as a major load from appliances, known to occur only in the morning, etc), before selecting the peak load hour for the overall calculation.

Cooling Load from Heat Gain through Roof, Exposed Walls, and Doors

Such loads are estimated using Equation (44), where the CLTDs are taken from Table 30 after determining appropriate type numbers from Table 31 whose insulation placement, U-factors and general construction are as close to the actual components as possible. Corrections to CLTD values are made in accordance with footnote instructions to Table 30 similar to the above preliminary evaluation. (Note that there are no corrections to CLTD values for building mass variations, per the foregoing discussion, as considered of only limited significance to the overall results. Tabulated data for roofs, walls and doors assume Room Transfer Functions for "light to medium" construction.)

Cooling Load from Heat Gain through Fenestration Areas

The load component from conduction heat gain is calculated using Equation (45), where the CLTD value is taken from Table 34, corrected by −1 °F because of a 1 °F lower average daily temperature than that for which the table was generated, and +3 °F to recognize the 75 °F design space temperature. The U-factor of the glass is taken as 0.81 Btu/(h · ft² · °F) for single sheet plate glass, under summer conditions.

The load component from solar heat gain is calculated using Equation (46) as indicated above. A shading coefficient (SC) of 0.55 is used for clear glass with light-colored venetian blinds. SCL values are taken from Table 36 in this chapter, after first identifying the appropriate zone type as B for solar load from Table 35A. Results are tabulated in Table 40.

Cooling Load from Heat Gain through Party Walls

For the north and west party walls, cooling load is calculated using Equation (16) for wall and door areas, using appropriate U-factors from Chapter 22 and the temperature differential existing at 1600 h, 18.4 °F. Results are tabulated in Table 41.

Cooling Load from Internal Heat Sources

For the cooling load component from lights, Equation (9) is first used to obtain the heat gain. Assuming a use factor of 1.0, and a special allowance factor of 1.0 for tungsten lamps and 1.20 for fluorescent lamps, these gains are:

$$q_{tung} = 4000 \times 1.0 \times 1.0 \times 3.41 = 13{,}640 \text{ Btu/h}$$

$$q_{fluor} = 17500 \times 1.0 \times 1.2 \times 3.41 = 71{,}610 \text{ Btu/h}$$

Since the tungsten lamps are operated continuously, the previously stored radiant heat from this source currently being re-convected to the space equals the rate of new radiant heat from this source being stored, thus the cooling load from this source equals heat gain. The fluorescent lamps however are operated only 10 hours per day, 0800 through hour 1700, and thus contribute radiant heat to cooling load in a cyclic and somewhat delayed manner. From Table 35A, the zone type is identified as C for lighting loads, and from Table 38 a CLF value of 0.92 is obtained for lights which are operated for 10 hours, for a calculation hour 9 hours after the lights have been turned on. The cooling load from fluorescent lights for this estimate is thus:

$$q_{cl\,fluor} = 71{,}610 \times 0.92 = 65{,}881 \text{ Btu/h}$$

For people, Table 3 is used to select heat gains for seated occupants doing light office work, as 250 Btu/h per person, sensible, and 200 Btu/h, latent for 75 °F space temperature. The CLF for the sensible component is taken from Table 37 as 0.92, for a condition of 10 total hours in a

type C space and a load calculation taken 9 h after entry. Cooling load from people is thus estimated at:

$$q_{ps} = 85 \text{ people} \times 250 \times 0.92 = 19{,}550 \text{ Btu/h}$$

$$q_{pl} = 85 \text{ people} \times 200 = 17{,}000 \text{ Btu/h}$$

Cooling Load from Power Equipment and Appliances

For this example, none are assumed.

Cooling Load from Infiltration and Ventilation Air

As determined in Example 6, which illustrates the use of the TFM, ventilation for this building is established at 15 cfm/person, or 1275 cfm, and infiltration (through doors) at 67 cfm. For this example, ventilation is assumed to enter directly into the space (as opposed to first passing through the cooling equipment), and thus is included as part of the space cooling load.

The sensible and latent portions of each load component are calculated using Equations (20) and (23), respectively, where at 1600 h: $t_o = 93.4$°F; $t_i = 75$°F; $W_o = 0.0161$; and $W_i = 0.0093$; thus:

For ventilation:

cfm	Factor	$t_o - t_i$	$W_o - W_i$	Btu/h
1275	1.1	18.4		25,806 Sensible
1275	4840		0.0068	41,963 Latent

For infiltration:

cfm	Factor	$t_o - t_i$	$W_o - W_i$	Btu/h
67	1.1	18.4		1,356 Sensible
67	4840		0.0068	2,205 Latent

Limitations of CLTD/SCL/CLF Methods

The results obtained from using CLTD/CLF data depend on the characteristics of the space and how they vary from those used to generate the weighting factors. Variations can appear in the amplitude and when radiant heat gain components are felt as cooling loads, which affect the hourly cooling loads for the space. Two types of error are possible:

1. The computer software that generated CLTD/SCL/CLF tables uses the TFM to determine cooling loads based on various types of heat gain. The cooling loads for each type of heat gain are normalized appropriately to obtain CLTDs, SCLs, or CLFs. Except, as discussed next, use of the CLTD/SCL/CLF method in conjunction with these tables will yield the same results as the TFM, but only when the same 14 zone parameters are specified.

   Three inherent errors in the TFM are carried through to the CLTD/SCL/CLF data:

   a. Each set of weighting factors or conduction transfer function coefficients are used for a group of walls, roofs, or zones with similar thermal response characteristics. Groups were chosen so that error would be minimal and conservative (Harris and McQuiston 1988, Sowell 1988).
   b. The scheme used for calculating weighting factors is based on 14 discrete parameters applied to a rectangular room. Rarely does a room fit exactly into these parameters. Therefore, engineering judgment must be used to choose the values of the 14 parameters that most closely represent the room for which load calculations are being performed.

Table 42 Potential Errors for Roof and Wall CLTDs in Tables 30 and 32

Roof No.	Error, %		Wall No.	Error, %	
	Plus	Minus		Plus	Minus
1	13	5	1	18	7
2	13	5	2	17	8
3	12	5	3	17	7
4	13	5	4	16	7
5	11	4	5	13	8
6	—	—	6	14	6
7	—	—	7	12	6
8	10	4	—	—	—
9	10	4	9	13	6
10	9	3	10	10	6
11	—	—	11	8	3
12	—	—	12	4	7
13	7	4	13	4	4
14	5	4	14	5	8
15	—	—	15	11	6
16	—	—	16	8	7

Note: Percent error = [(Table Value − TFM Value)/TFM Value] × 100

Deviations of the room from the available levels of the 14 parameters may result in errors that are not easily quantifiable.

c. A fundamental presupposition of the TFM is that total cooling load for a zone can be calculated by simple addition of the individual components. For example, radiation heat transfer from individual walls and roofs is assumed to be independent of the other surfaces. O'Brien (1985) has shown this assumption can cause some error.

2. The printed tables for CLTDs, SCLs, and CLFs have undergone a further grouping procedure. The maximum potential errors due to the second grouping procedure have been analyzed and are tabulated in Tables 35 and 42. These errors are in addition to those inherent in the TFM. However, for usual construction, these errors are modest.

In summary, the CLTD/SCL/CLF method, as with any method, requires engineering judgment in its application. When the method is used in conjunction with custom tables generated by appropriate computer software (McQuiston and Spitler 1992) and for buildings where external shading is not significant, it can be expected to produce results very close to those produced by the TFM. When the printed tables are used, some additional error is introduced. In many cases, the accuracy should be sufficient.

TETD/TA CALCULATION PROCEDURE

To calculate a space cooling load using the TETD/TA convention, the same general procedures for data assembly and precalculation analysis apply as for the TFM. Similarly, the following factors are handled in an identical manner and are not repeated here.

- Basic heat gain calculation concepts of solar radiation (solar and conductive heat gain through fenestration areas, conversion to cooling load)
- Total heat gain through exterior walls and roofs (sol-air temperature, heat gain through exterior surfaces, tabulated temperature values, surface colors, air temperature cycle and adjustments, average sol-air temperature, hourly air temperatures, and data limitations)
- Heat gain through interior surfaces (adjacent spaces, floors)
- Heat gain through infiltration and ventilation

This section describes how the TETD/TA technique differs from the TFM. For sources of the space cooling load, equations, appropriate references, tables, and sources of other information for an overall analysis, see Table 43.

Treatment of Heat Gain and Cooling Load Conversion Procedures

As originally presented in the 1967 and 1972 editions of the *Handbook of Fundamentals*, the TETD/TA method was oriented primarily as a manual procedure. Tables of precalculated time-lags, decrement factors, and total equivalent temperature differential values listed a number of representative wall and roof assemblies, for use in the appropriate heat gain equations. These data were based on a Fourier series solution to the one-dimensional unsteady-state conduction equation for a multiple-component slab, as used to calculate the heat flow through each of the walls and roofs selected for that purpose. All calculations were based on an inside air temperature of 75 °F and a sol-air temperature at the outside equal to those given in Table 1 for horizontal and vertical surfaces of various orientations, at 2-h increments throughout a typical design day, as outlined by Stewart (1948) and Stephenson (1962). Basic equations were also presented to facilitate a computer solution.

Heat gain through walls and roofs. The results of the foregoing calculations were generalized by dividing the derived hourly heat gain values by the U-factor for each typical wall and roof. The quantity obtained from this generalization is called the total equivalent temperature differential (TETD). This establishes the basic heat gain equation for exterior surfaces as:

$$q = UA(\text{TETD}) \tag{51}$$

where

q = heat gain, Btu/h
U = coefficient of heat transfer, Btu/(h·ft²·°F)
A = area of surface, ft²
TETD = total equivalent temperature differential (as above)

It is assumed that the heat flow through a similar wall or roof (similar in thermal mass as well as U-factor) can be obtained by multiplying the TETDs listed in the appropriate table by the U-factor of the wall or roof of interest. Any errors introduced by this approach depend on the extent of the differences between the construction in question (components, size, color, and configuration) and the one used for calculating the TETDs.

TETD as function of decrement and time lag factors. The heat gain results for representative walls and roofs were also generalized in another way. Effective decrement factors λ and time lags δ were determined for each assembly, such that the equivalent temperature differentials and the corresponding sol-air temperatures are related by:

$$\text{TETD} = t_{ea} - t_i + \lambda(t_{e\delta} - t_{ea}) \tag{52}$$

where

t_{ea} = daily average sol-air temperature, including consideration for surface color
t_i = indoor air temperature
λ = effective decrement factor
$t_{e\delta}$ = sol-air temperature δ hours before the calculation hour for which TETD is intended

This relationship permits the approximate calculation of the heat gain through any of the walls or roofs tabulated, or their near equivalents, for any sol-air temperature cycle.

Manual versus automated calculation. Manual application of the TETD/TA procedure, especially the time-averaging calcu-

Table 43 Summary of TETD/TA Load Calculation Procedures

External Heat Gain

$$t_e = t_o + \alpha I_t/h_o - \epsilon\delta R/h_o \quad (6)$$

$$t_{ea} = t_{oa} + \alpha/h_o(I_{DT}/24) - \epsilon\delta R/h_o \quad (7)$$

t_e = sol-air temperature
t_o = current hour dry-bulb temperature, from design db (Chapter 24, Table 1) adjusted by Table 2 daily range % values
α = absorptance of surface for solar radiation
α/h_o = surface color factor = 0.15 for light colors, 0.30 for dark
I_t = total incident solar load = 1.15(SHGF), with SHGF per Chapter 27, Tables 12 through 18
$\epsilon\delta R/h_o$ = long-wave radiation factor = −7°F for horizontal surfaces, 0°F for vertical
t_{ea} = 24-h average sol-air temperature
t_{oa} = 24-h average dry-bulb temperature
I_{DT} = total daily solar heat gain (Chapter 27, Tables 12 through 18)

Roofs and Walls

$$q = UA\,(\text{TETD}) \quad (51)$$

$$\text{TETD} = t_{ea} - t_i + \lambda(t_{e\delta} - t_{ea}) \quad (52)$$

U = design heat transfer coefficient for roof or wall, from Chapter 22, Table 4
A = area of roof or wall, calculated from building plans
TETD = total equivalent temperature difference, roof or wall
t_i = interior design dry-bulb temperature
λ = decrement factor, from Table 14 or 19
$t_{e\delta}$ = sol-air temperature at time lag δ hours (Table 14 or 19) previous to calculation hour

Roofs

Identify layers of roof construction from Table 11.

With R-value of dominant layer, identify R-value Range number R and Roof Group number from Table 12. From Table 14 obtain decrement factor and time lag data with which to calculate TETD values for each sol-air temperature value by Equation (52). Calculate hourly heat gain with Equation (51).

Walls

Identify layers of wall construction from Table 11.

With R-value of dominant layer, identify R-value Range number R and Wall Group number from Tables 15, 16, or 17.

Glass

$$\text{Convective } q = UA\,(t_o - t_i)$$

$$\text{Solar } q = A\,(\text{SC})(\text{SHGF})$$

U = design heat transfer coefficients, glass—Chapter 27, Tables 1, 2, 5, and 6
SC = shading coefficient—Chapter 27
SHGF = solar heat gain factor by orientation, north latitude, hour, and month—Chapter 27, Tables 12 through 18

Partitions, Ceilings, Floors

$$q = UA\,(t_b - t_i) \quad (8)$$

t_b = temperature in adjacent space
t_i = inside design temperature in conditioned space

Internal Heat Gain

People

$$q_{sensible} = N\,(\text{Sensible heat gain})$$

$$q_{latent} = N\,(\text{Latent heat gain})$$

N = number of people in space, from best available source

Sensible and latent heat gain from occupancy—Table 3, or Chapter 8; adjust as required

Lights

$$q_{el} = 3.41\,WF_{ul}\,F_{sa} \quad (9)$$

W = watts input from electrical plans or lighting fixture data
F_{ul} = lighting use factor, from the first section, as appropriate
F_{sa} = special allowance factor, from first section, as appropriate

Power

$$q_p = 2545\,PE_F \quad (15), (16), (17)$$

P = horsepower rating from electrical plans or manufacturer's data
E_F = efficiency factors and arrangements to suit circumstances

Appliances

$$q_{sensible} = q_{is}\,F_{ua}\,F_{ra} \quad (18)$$

or

$$q_{sensible} = (q_{is}\,F_{ua}\,F_{ra})/F_{fl} \quad (20)$$

$$q_{latent} = q_{il}\,F_{ua} \quad (22)$$

q_{is}, q_{il} = sensible and latent heat gain from appliances—Tables 5 to 9, or manufacturer's data (set latent heat = 0 if appliance under exhaust hood)
F_{ua}, F_{ra}, F_{fl} = use factors, radiation factors, flue loss factors

Ventilation and Infiltration Air

$$q_{sensible} = 1.10\,Q\,(t_o - t_i) \quad (25)$$

$$q_{latent} = 4840\,Q\,(W_o - W_i) \quad (27)$$

$$q_{total} = 4.5\,Q\,(H_o - H_i) \quad (23)$$

Q = ventilation from ASHRAE *Standard* 62; infiltration from Chapter 23
t_o, t_i = outside, inside air temperature, °F
W_o, W_i = outside, inside air humidity ratio, lb water/lb dry air
H_o, H_i = outside, inside air enthalpy, Btu/lb dry air

Cooling Load

Sensible

$$q_{sensible} = q_{cf} + q_{arf} + q_c$$

$$q_{cf} = [q_{s,1}(1 - rf_1)] + [q_{s,2}(1 - rf_2)] + \ldots rf_n)]$$

$$q_{arf} = \sum_{\gamma = h_{a+1-\theta}}^{\theta} [(q_{s,1} \times rf_1) + (q_{s,2} \times rf_2) + \ldots rf_n)_\gamma] / \theta$$

$$q_c = (q_{sc,1} + q_{sc,2} + q_{sc,\beta})$$

$q_{sensible}$ = sensible cooling load, Btu/h
q_{cf} = convective fraction of hourly sensible heat gain (current hour) for n load elements, Btu/h
$q_{s,1}$ = sensible hourly heat gain for load element 1, ... n
rf_1 = radiant fraction (Table 44) of sensible hourly heat gain for load element 1, ... n
q_{arf} = average of radiant fractions of hourly sensible heat gain for n load elements, Btu/h
θ = number of hours over which to average radiant fractions of sensible heat gain
h_a = current hour, 1 to 24, for which cooling load is to be calculated
γ = one of calculation hours, from $h_{a+1-\theta}$ to h_a, for which the radiant fraction of sensible heat gain is to be averaged for each of n load elements
q_c = convective hourly sensible heat gain (current hour) for β load elements having no radiant component, Btu/h

Latent

$$q_{latent} = (q_{l,1} + q_{l,2} + q_{l,\beta})$$

q_{latent} = latent cooling load, Btu/h
q_l = hourly latent heat gain (current hour) for β load elements, Btu/h

lation itself, is tedious in practice. This fact, plus growing interest in the TFM, led to ASHRAE research with the objective of comparing the differences and similarities of the TETD and TFMs.

Later research completed the circle of relationships between the TFM, its subsystem CLTD/CLF, and the TETD/TA techniques for dealing with the conversion of heat gain to cooling load. It also confirmed the logic of maintaining these various approaches to solving the problem, depending on the orientation and needs of the individual user and the means available. Finally, the research showed no further need to continue developing manual TETD/TA procedures. Thus, the tabulated values of TETDs have been eliminated from this Handbook in favor of calculation of TETD values by use of the material in the previous section that discusses the TFM.

U-Factors. The values for TETD, originally tabulated in the 1967 *Handbook of Fundamentals*, were calculated using an outside surface conductance of 3.0 Btu/(h·ft²·°F) and an inside surface conductance of 1.2 Btu/(h·ft²·°F), and thus should most appropriately be used with U-factors based on the same surface conductances. TETD data tabulated in the 1972 *Handbook of Fundamentals* and all data listed in this chapter are based on outside and inside surface conductances of 3.0 and 1.46, respectively. U-factors listed in Tables 14 for roofs and 19 for walls can, however, be used with the 1972 TETD data with negligible error, while calculated TETD values are directly compatible with the Table 14 and 19 U-factors.

Example 12. Wall heat gain by TETD. A wall is constructed of 4 in. heavy concrete, 2 in. insulation (2.0 lb/ft³, R = 6.667 h·ft²·°F/Btu), 3/4 in. indoor plaster, and with outdoor and indoor surface resistances of 0.333 and 0.685 h·ft²·°F/Btu, respectively. There is an air space between the plaster and the insulation. The wall faces west, the outside design temperature is 95 °F, the outdoor daily range is 21 °F, the indoor temperature is 75 °F, and the color of the exterior surface is light (α/h_o = 0.15). The time is 1400 h on a July day in the central part of the United States (40 °N latitude).

Find the heat gain per square foot of wall area.

Solution: Turning first to Table 11, the code numbers for the various layers of the wall described above are:

Outside surface resistance	= A0
4 in. heavyweight concrete	= C5
2 in. insulation	= B3
Air space resistance	= B1
3/4 in. plaster	= E1
Inside surface resistance	= E0

Construction of the wall being "mass out" (as defined in TFM section), Table 17 represents the appropriate arrangement of layers. The dominant wall layer C5 is indicated to have a Wall Material column number of 10, which, combined with an E1 layer, dictates use of the upper array of code numbers for wall assembly "groups." Entering this array with an R value range of 9 (R = 6.667) indicates under column 10 that Wall Group 7 is that most nearly representative of the wall under consideration. The appropriate data from Wall Group 7 as listed in Table 19 are:

h = 5.14 = time lag, h

λ = 0.41 = effective decrement factor

U = 0.122 = heat transfer coefficient, Btu/(h·ft²·°F)

For this example, the sol-air temperature value for 1400 h t_e, as listed in Table 1, is 121 °F, that for 0900 h (5 h earlier) is 85 °F, and the daily average is 91 °F. Thus, from Equation (52):

$$TETD = 91 - 75 + [0.41(85 - 91)] = 13.54\,°F$$

and from Equation (51)

$$q = 0.122 \times 1 \times 13.54 = 1.65\ Btu/(h \cdot ft^2)$$

Roof heat gain by TETD. The procedure for estimating heat gain from an exposed roof assembly is similar to that described for a wall—first identifying the code letters for the various layers from Table 11; identifying the appropriate roof group number from Table 12; reading the time lag, effective decrement factor, and U-factor for the selected roof group from Table 14; calculating the TETD for the hour of interest from these data and reference to Table 1; and then calculating the heat gain by means of Equation (51).

Heat gain from adjacent unconditioned spaces. In a manner similar to that described for the TFM, heat gain from adjacent unconditioned spaces can be estimated in two ways, depending on the thermal storage characteristics of the intervening surface. When storage effect is minor, sufficient accuracy can be obtained by use of Equation (8); otherwise, the appropriate TETD value should be calculated by the manner described for an exposed wall surface and the heat gain calculated by Equation (51).

Instantaneous heat gain from all other sources. Conductive and solar heat gain through fenestration, heat gain from the various internal sources (*e.g.*, people, lighting, power, appliances, etc.), heat gain due to infiltration and ventilation, and latent heat gain from moisture through permeable building surfaces are each calculated in the same manner as described in the TFM section. The basic differences in calculation techniques between TFM and TETD/TA lie in the manner in which the heat gain data are converted to cooling load, as described later.

COOLING LOAD BY TIME AVERAGING

The time-averaging technique for relating instantaneous heat gain to instantaneous cooling load is an approximation of the TFM two-step conversion concept. It recognizes thermal storage by building mass and contents of the radiant portions of heat gain entering a space at any time, with subsequent release of stored heat to the space at some later time. It further recognizes that the cooling load for a space at a given hour is the sum of all convective heat gain and the nonradiant portion of conductive heat gain to that space, plus the amount of previously stored radiant heat gain released back to the space during that same hour.

The effect of room transfer coefficients on hourly heat gain is to generate a load profile that tracks the instantaneous heat gain in amplitude (greater or lower) and delay (negligible for very light structures with a predominance of glass, up to several hours for very massive, monumental construction). Being functions of the mass and configuration of the building and its contents, such coefficients place major emphasis on the immediately preceding hour, and rapidly lessening emphasis on each hour previous to that.

Such TFM-generated cooling load profiles can be closely approximated by averaging the hourly radiant components of heat gain for the previous one to seven or eight hours with those for the current hour, and adding the result to the total convective heat gain for the current hour. As long as results are consistent with results from the more rigorous TFM analysis, those from TETD/TA can be obtained with far less computational effort. The convenient ability to vary the averaging period independently (in recognition of previous experience of the probable thermal performance of an individual building) is also a valuable means of exerting professional judgment on the results.

Success of this approach depends on the accuracy with which the heat gain components are broken down into convective and radiant percentages, as well as on the number of hours used for the averaging period. Weakness of this approach lies in the absence of verified data in the technical literature regarding either determining factor, and the corresponding necessity for experienced judgment by the user.

Heat gain values for either the TFM or TETD/TA method are essentially identical for all load components. Derived cooling load values from properly applied averaging techniques closely track those from the TFM for external heat gain sources. Cooling loads from internal heat gains, however, averaged over the same period as for the external components, normally have peaks that occur more quickly and with greater amplitudes (up to full value of the source heat gain) than those generated by the TFM. This difference is due primarily to the almost constant level of radiant heat input during the occupied periods and the resultant "flattening" of the cooling load curves by the TFM as discussed in the TFM section.

The conservative results obtained from the time-averaging method compared with those of the TFM should be viewed in proper perspective. In the CLTD technique, for example, CFL values profile internal loads as a function of time in the space (up to the hour of interest) versus total time to be in effect during the day, and the tabulated fractional values are used *only* when HVAC equipment is operated 24 h a day and space temperature is not allowed to rise during unoccupied periods; otherwise, internal heat gains are considered instantaneous cooling loads at *full* value. On the other hand, the TFM, while not dealing directly with individual load components when space temperatures are permitted to rise overnight, applies space air transfer functions to estimate resultant increased rates of total sensible heat extraction from that space during periods of equipment operation. Regardless of methodology, good engineering judgment must be applied to predict realistic cooling loads from internal heat gains.

Time-averaging data in this chapter are empirical and offered only as information found dependable in practice by users of the technique. Basic assumptions regarding the percentages of radiant heat gain from various sources are used as default values by the TFM in establishing envelope transfer coefficients and room transfer coefficients. The TETD/TA method requires a specific breakdown by the user to determine what values are to be averaged over time. Table 44 suggests representative percentages for this purpose.

The convective portion of heat gain is treated as instantaneous cooling load. The radiant portion of instantaneous heat gain is considered as reduced or averaged over time by the thermal storage of the building and its contents. For lightweight construction, the instantaneous cooling load may be considered as an average of the radiant instantaneous heat gain over a 1 to 3-h period up to and including the hour of calculation interest, plus the nonradiant component of that hour's heat gain. For very heavy construction, the averaging period for hourly values of radiant instantaneous heat gain may be as long as 6 to 8 h, including the hour of calculation interest. Most users of this technique rarely consider application of an averaging period longer than 5 h, with a general norm of 3 h for contemporary commercial construction.

Table 44 Convective and Radiant Percentages of Total Sensible Heat Gain for Hour Averaging Purposes

Heat Gain Source	Radiant Heat, %	Convective Heat, %
Window solar, no inside shade	100	—
Window solar, with inside shade	58	42
Fluorescent lights	50	50
Incandescent lights	80	20
People	33	67
Transmission, external roof and walls	60	40
Infiltration and ventilation	—	100
Machinery and appliances[a]	20 to 80	80 to 20

[a]The load from machinery or appliances varies, depending on the temperature of the surface. The higher the surface temperature, the greater the percentage of heat gain that is radiant.

The two-step nature of the TETD/TA procedure offers a unique convenience in calculating cooling load through externally shaded fenestration. As described in the beginning of this section, the hourly history of fenestration heat gain as modified by external shading devices is directly usable for averaging purposes. Thus, the engineer has excellent control and can readily use the effect of external shading on cooling load in the conditioned space. Sun (1968) identified convenient algorithms for analysis of moving shade lines on glass from external projections.

EXAMPLE COOLING LOAD CALCULATION USING TETD/TA

Example 13. Cooling load calculation of small office building. For this example, the one-story building used to illustrate the TFM in Example 6 (and indicated in Figure 4) is also used for calculating a cooling load by the TETD/TA method. Refer to Example 6 for the statement of conditions.

Find (for stated design conditions):

1. Sensible cooling load
2. Latent cooling load
3. Total cooling load

Solution: By TETD/Time-averaging method.

1. Daily Load Cycle

The cooling loads are calculated once per hour for a period of time necessary to cover the hour of anticipated peak design load. For the purposes of this example, the full range of loads over a typical 24-h cycle are presented.

2. Hourly Heat Gain Components

Hourly heat gain values for each load component must be calculated for the same range as those for the cooling load, plus as many preceding hours as will be needed for the purposes of time-averaging (in the case of this example, all 24-h values have been calculated). The methodology involving use of time lag, effective decrement factor, and calculated TETD values is used to calculate heat gain components through walls and roof.

3. Thermal Storage

The heat storage effect of the room is accounted for by averaging the radiant elements of heat gain components for the hour in question with those of the immediately previous hours making up the selected averaging period, and combining the result with the convective heat gain elements for the current hour.

4. Summary

The data and summary of results using TETD/TA are tabulated in Table 45. Following the table is a step by step description of the calculation procedure used to determine the values listed.

1. **Sensible Cooling Load**

(a) General

Line 1, Time of day in hours. Various temperatures and heat flow rates were calculated for every hour on the hour, assuming that hourly values are sufficient to define the daily profile.

Line 2, Outside air temperatures. Hourly values were derived by the procedure given previously, using the specified maximum dry-bulb temperature of 94°F and daily range of 20°F.

(b) Solar Heat Gain Factors

Lines 3, 4, 5, and 6, Solar heat gain through opaque surfaces. The values in these columns are copies of the SHGF values listed in Table 4 for July 21 and 40°N latitude. These SHGF values are used to calculate sol-air temperatures of various outside surfaces, and solar heat gain through windows.

The June values might have been used, since the solar irradiation of horizontal surface (i.e., roof) is maximum at that time of year and since the heat gain through the roof appears to be the major component of exterior heat gain in this example problem. The difference between June and August values is relatively small however, compared to the large percentage increase in solar heat gain through south glass in August versus June at this latitude, thus indicating that August might be the better choice. For this example, data for July were selected as reasonable, and to provide better comparison with the results from other techniques for which tabular data are limited. For better assurance of accuracy it is preferable to evaluate

and compare the relative loads of various surfaces for several months, before making a final determination as to that in which the maximum load will occur.

(c) Sol-Air Temperatures

Lines 7, 8, 9, and 10, Sol-air temperatures at opaque surfaces. Sol-air temperatures were calculated by Equation (6).

(d) Total Equivalent Temperature Differentials

Lines 10a through 10h, Calculated TETD values. Hourly TETD values for each of the expose surfaces, are calculated by Equation (52) to incorporate individual thermal characteristics and orientation.

Line 10a, Roof TETD. Referring to Table 11, the major element of the roof (that with the most mass) is the gypsum slab with code number C14. Other elements are the metal deck (A3), rigid insulation (B3), built-up roofing (E3), and gravel surface (E2). Entering Table 12 with these data, the C14 roof slab with no ceiling and R values of 11.11 calls for an R range of 3. From the "mass-in" part of the upper table these pointers indicate roof group 5 as that whose thermal characteristics will best represent the roof in question.

The time lag and effective decrement factors are then obtained from Table 14, as tabulated for roof group 5. These values are:

Time lag = 4.82 h

Effective decrement factor (λ) = 0.68

The TETD values were then calculated for the roof surface with Equation (52), using the sol-air temperature cycle given in line 7 and t_i = 75 °F.

Lines 10b through 10e, Wall TETD. The TETD values for the various walls were calculated by the same approach as that described for the roof. Time lag and effective decrement factors were selected from Table 19, as:

North and East Exterior Walls

Dominant element C8, from Table 11;
Interior finish E1 from Table 11;
R value indicating R range of 2 from Table 16 (integral mass);
C8 dominant layer indicating Material Layer 13 from Table 16;
From Table 16 select Wall Group 5 from the upper section (combining Layer 13 with E1 finish) as the most representative, and thus obtain the time lag and decrement factors from Table 19 as 5.11 h and 0.64 DF, respectively.

South Wall

Dominant element C9, or Layer 14 in Integral mass table;
Exterior layer A2 or A7;
Interior layer E1 (plywood panel ignored as trivial);
R value indicating *R* of 6;
Select wall group 24 for representative performance factors of 11.29 h and 0.23 DF.

North and West Party Walls

With no specific data for a 13 in. brick wall, use a layer of 8 in. common brick (C9) and a layer of 4 in. face brick (A2 or A7) as an approximation;
Dominant element C9, or Layer 14 in Integral Mass table;
Exterior layer A2 or A7;
R value indicating R of 6;
Select wall group 24 for representative factors 11.29 h and 0.23 DF. Calculate TETD values as above.

Lines 10f, 10g, and 10h, Door TETD values. Heat storage of the doors may be assumed negligible, and the heat gain, therefore, is calculated with Equation (8) as:

$$q_{DT} = U_D A_D (t_{DT} - t_i)$$

where

U_D = 0.19; U-factor of doors (0.18 for interior doors)
A_D = 35; area of a door, ft²
t_i = 75 °F, inside temperature
t_{DT} = outside temperature. For the door in the north party wall, t_{DT} equals outside air temperature. For the doors in east and south walls t_{DT} equals the east and south wall sol-air temperatures, respectively.

While the foregoing calculation would be reasonable in estimating the minor loads involved, for this example, the relatively brief storage effect of the solid core doors has been considered as:

Dominant element B7, or Layer 3 in Integral Mass table;
Interior finish A6;
R-factor indicating R range of 8;

Select wall group 1 for representative time lag of 1.30 h and 0.98 DF, and follow the above procedures to calculate the associated TETD values.

(e) *Instantaneous Sensible Heat Gain*

Line 11, Roof heat gain. Instantaneous heat gain through the roof, calculated with Equation (51) and the TETD values on line 10a.

Lines 12 through 18, Wall and door heat gain. The instantaneous heat gains through the various walls and doors were calculated the same way as heat gain through the roof was calculated. TETD values from lines 10b through 10h were used in Equation (51).

Lines 19, 20, and 21, Window heat gain. The air to air heat gain (line 19) is

$$q_{a-a} = U_w A_w (t_{o\theta} - t_i)$$

where

U_w = 0.81; U-factor of window
A_w = 90; area of windows
$t_{o\theta}$ = outside air temperature at hour θ

The solar radiation heat gain (Lines 20 and 21) through south and north windows is:

$$q_r = A_w \mathrm{SC} (\mathrm{SHGF})_\theta$$

where

$(\mathrm{SHGF})_\theta$ = Solar heat gain factors given in line 5 for south and line 6 for north
SC = 0.55; shading coefficient for clear window with light-colored curtain or blind

Lines 22 and 23, Heat gain from tungsten and fluorescent lights. For the gain from lighting, Equation (9) was used with a use factor of unity, and special allowance factors of 1.20 for the fluorescent lamps and of unity for the tungsten lamps. Thus:

$q_{el\,tung}$ = 4000 × 1 × 1 × 3.41 = 13,640 Btu/h, and

$q_{el\,fluor}$ = 17500 × 1 × 1.20 × 3.41 = 71,610 Btu/h

Line 24, People. Sensible heat gain due to people. For the occupants, the data of Table 3 was used for moderately active office work. Thus:

q_p = (Number of people)(Sensible heat generated per person)
= 85 × 250 = 21,250 Btu/h

Lines 25 and 26, Sensible heat gain from infiltration and ventilation. As developed previously, the value to be used for infiltration was established as 67 cfm, and that for ventilation as 1275 cfm. Heat gain from all air entering as infiltration is routinely part of the space load. In the case of this example (since ventilation is delivered directly to the space, rather than first through the cooling equipment), its gain is also included as a direct space load. (Note: Had the ventilation air instead been mixed with return air after leaving the occupied space and before entering the cooling equipment, only that portion which passed through the cooling coil without being treated by it—as a function of the coil inefficiency or "Bypass Factor," which is normally 3 to 5% for a chilled water coil of 6 or more rows and close fin spacing to 15% or more for refrigerant coils in packaged air-conditioning units—and/or that quantity deliberately bypassed around the coil in response to a "face and bypass" or "conventional multizone" space dry-bulb temperature control scheme, would become a part of the space heat gain as such rather than a part of the cooling coil load per se. While potentially of major significance to the overall design of a cooling system, the detailed treatment of this concept is beyond the scope of this chapter. Refer to the 1992 ASHRAE *Handbook—Systems and Equipment* for assistance.)

The sensible loads are determined from Equation (20). At 1500 hours for example, when t_o = 94°F and t_i = 75°F, this generates:

$$q_{si} = 1.1 \text{ (Infiltration rate, cfm)}(t_o - t_i)$$
$$= 1.1 \times 67(94 - 75) = 1400 \text{ Btu/h, and}$$

$$q_{sv} = 1.1 \text{ (Ventilation rate, cfm)}(t_o - t_i)$$
$$= 1.1 \times 1275(94 - 75) = 26{,}600 \text{ Btu/h}$$

Line 27, Total instantaneous sensible heat gain. The sum of sensible heat gain values on lines 11 through 26 for each calculation hour. This represents the total amount of such gain that actually enters the building during each hour, including any delaying effects of the individual surfaces on the passage of heat, but before any consideration of the storage and subsequent release of the radiant components of such heat.

(f) Instantaneous Latent Heat Gain

Line 28, People. The latent heat gain due to people, using Table 3 data

= (number of persons)(latent heat generated by one person)
= 85 × 200 = 17,000 Btu/h during the occupied period

Lines 29 and 30, Latent heat gain from infiltration and ventilation. The latent loads are determined from Equation (23). At 1500 h for example, when W_o = 0.0161 and W_s = 0.0093, this generates:

$$q_{li} = 4840 \text{(Infiltration rate, cfm)}(W_o - W_s)$$
$$= 4840 \times 67(0.0161 - 0.0093) = 2205 \text{ Btu/h, and}$$

$$q_{lv} = 4840 \text{(Ventilation rate, cfm)}(W_o - W_s)$$
$$= 4840 \times 1275(0.0161 - 0.0093) = 41{,}963 \text{ Btu/h}$$

Line 31, Total latent heat gain. The total latent heat gain is the sum of lines 27, 28, and 29.

(g) *Total Instantaneous Heat Gain*

Line 32, Total instantaneous heat gain. The sum of total instantaneous values on lines 27 and 31, sensible and latent heat gain, respectively. The hourly profile of such a total will normally reach a higher level at an earlier time of day than that of the building total cooling load, although the 24-h totals will be identical.

(h) *Cooling Load from Convective Sensible Heat Gain Components*

Lines 33 through 38. Direct inclusion of the instantaneous heat gain components listed in Lines 19, 25, and 26, and 20%, 50%, and 67% of lines 22, 23, and 24, respectively. These room sensible heat gain components (*i.e.*, loads due to air-to-air heat gain through windows, tungsten lights, fluorescent lights, people, infiltration, and ventilation) all appear as cooling load without delay. Percentages of sensible heat gain considered convective are taken from Tables 3 and 42. Selection of 67% of sensible gain from people as convective is an approximation for purposes of this example.

(i) *Cooling Load Involving Time-Averaging Consideration*

Radiant elements of instantaneous heat gain will be felt as cooling load in the space only after having first been absorbed by the mass of building and contents, and later released back into the space as convective heat. This delaying action is approximated by time-averaging, or taking the average of such a heat gain value for the current hour with those from some number of immediately previous hours. An averaging period of about 5 h is used for this example, in which, for example, the value of cooling load for hour 1200 is derived as the average of the radiant fractions of hourly sensible heat gain for hours 1200, 1100, 1000, 0900, and 0800; thus delaying the full impact of such heat gain becoming cooling load for 5 h, and extending the period after the heat gain has ended for some amount of cooling load to be felt by the space.

Line 39, Cooling load from tungsten light sensible heat gain. Although 80% of the sensible heat gain from tungsten lights is radiant heat and subject to the storage/re-release phenomenon, data on line 39 appears as a constant value for every hour. This is due to the constant heat input to the room (line 22), from lights switched on all the time and thus with the radiant heat gain component from prior hours being released as cooling load at the same rate as the absorption by the room of the current hour's radiant component.

Line 40, Cooling load from lighting cycled on and off. Fifty percent (the radiant component) of the fluorescent lighting heat gain from line 23, showing the effect of such gain being processed by time-averaging, as indicated above.

Line 41, Cooling load due to radiant heat gain from people. Of sensible heat generated by people, 33% is dissipated by radiation and felt by the space as cooling load only after having been absorbed by the mass of the building and its contents.

(j) *Sensible Cooling Load from Exposed Surfaces*

Elements of instantaneous heat gain from solar radiation through windows, walls, doors and roof, *i.e.*, the sum of values listed in lines 11 through 18, 20, and 21, are also delayed in being felt as cooling. The radiant heat gain by solar radiation transmitted through windows is treated the same way as the radiant portion of heat gain through walls and roof surfaces. However, since the windows have inside shading devices, solar radiation is considered reduced to approximately 58% of the solar heat gain through glass because the venetian blind intercepts about 42% of such solar radiation and releases it to the room in a convective form, similar to the treatment of heat gain through walss and roof [see Table 44].

(*Note*: Had there been *no internal shading* of the glass, the solar radiation through windows would have to be treated as 100% radiant, all subject to time-averaging. Translucent draperies fall between these limits, in a linear relationship. Chapter 27 has more specific information on internal shading.

Lines 42a through 51a, Sensible cooling load from convective heat gain through enclosing surfaces. Data on lines 42b and 43b represent 58% of heat gain values for north and south windows, respectively, form lines 20 and 21, but time-averaged. Data for opaque enclosing surfaces on lines 44b through 51b represent 60% of the corresponding heat gain values on lines 11 through 18, but also time-averaged.

Cooling Load from power equipment and appliances. For this example, none are assumed. Had such loads been involved, with starting or ending periods within the time before the hour of calculation interest that can affect the averaging period, 20 to 80% of the sensible heat gain would have been considered as radiant and subject to time-averaging.

Line 52, Total room sensible cooling load. Total sensible cooling load felt by the room, and the design sensible load which is used as the basis for sizing cooling equipment. It is the sum of the values listed in lines 33 through 51b. The almost exact match between the 24-h total of 2,046,781 Btu/h on line 52 and the sum of the 24-h gain totals on line 27 (differing only by 16 Btu/h), while beyond reasonable limits of arithmetic precision, does verify completeness of the computation.

2. *Latent Cooling Load*

Line 31—The sum of lines 28, 29, and 30. Total latent heat gain is also the total latent cooling load, as all components occur instantaneously.

3. *Total Cooling Load*

Line 52, The sum of lines 52 and 31. The total cooling load for this example problem is the theoretical total for the conditions as defined, and may or may not represent the actual total cooling load imposed upon a system of cooling equipment attempting to maintain the specified space conditions. An appropriate psychrometric analysis of supply air, space air, return air, and mixed air [when ventilation air is mixed with return air enroute back to the cooling equipment] should be performed, in conjunction with proper consideration of the type of cooling equipment and characteristics of the preferred control scheme, in order to verify the ability of the design to meet the requirements, and to determine whether the actual sensible, latent, and total cooling loads are greater or less than the theoretical values calculated. The 1992 ASHRAE *Handbook—Systems and Equipment* has further information.

Comparison of Results

Each of the calculation procedures outlined in this chapter, TFM, CLTD/SCL/CLF, and TETD/TA have used the same building in Examples 6, 11, and 13, respectively. Although widely different in purpose, approach, and mathematical processes, the results have many similarities as illustrated by Figure 5.

Tabular data for hourly total instantaneous sensible heat gain and total sensible cooling load values from Tables 28 and 45 are plotted to compare the two computer-based techniques, TFM and TETD/TA. The curves for heat gain are almost identical. Those for cooling load, however, happen to peak at the same hour, 1600, but with different magnitudes. The TETD/TA cooling load peak has reached almost the peak of its com-

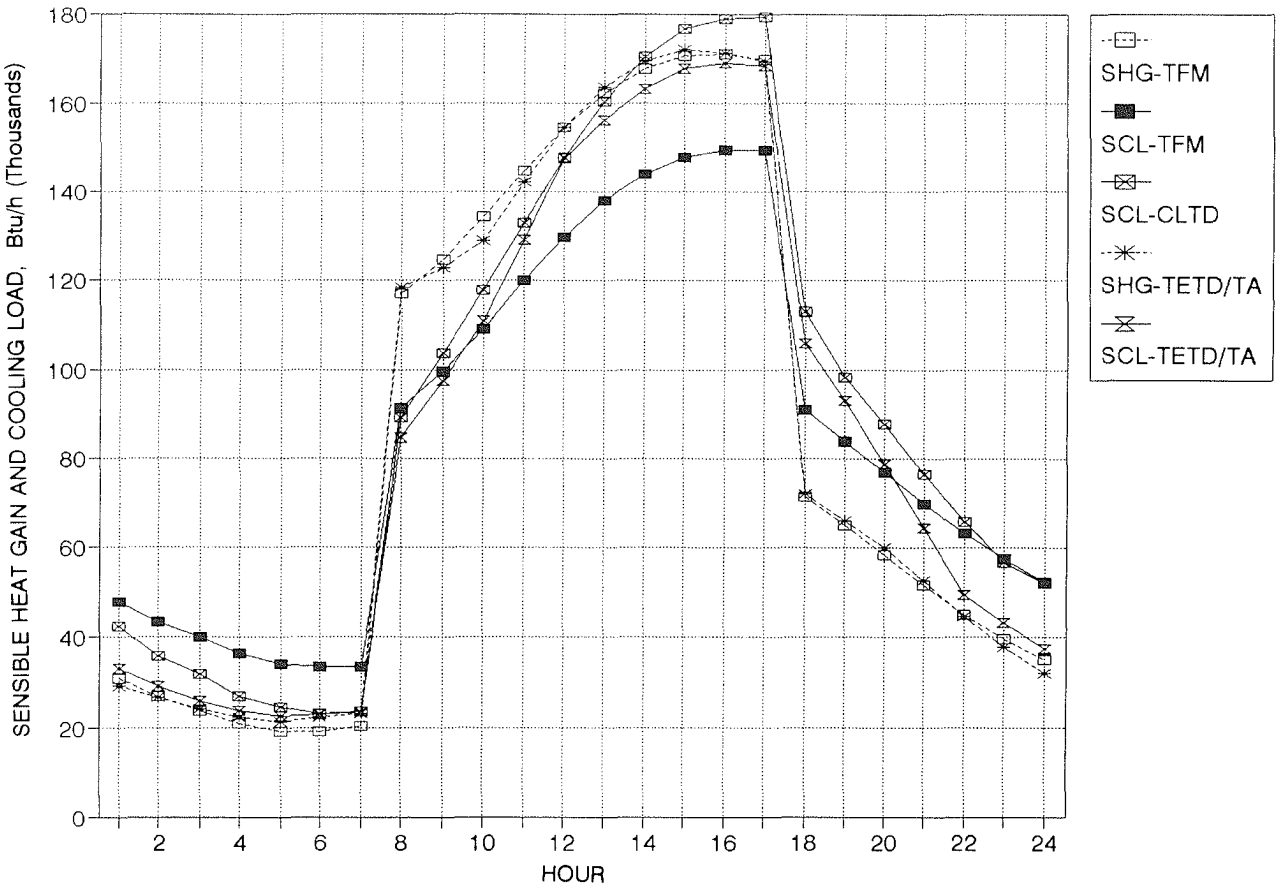

Fig. 5 TFM versus CLTD/SCF/CLF versus TETD/TA Methods of Calculating Sensible Heat Gain and Cooling Load

panion heat gain curve, but one hour later. The TFM heat gain curve reaches a peak at 1600 with a value only 0.5% different from that for TETD/TA, but the TFM cooling load curve peaks at only 87.5% of its heat gain curve. All unoccupied hours show substantially greater TFM cooling loads than for TETD/TA, while 24-h totals vary only by 0.15%.

As a manual procedure, Example 11, illustrating the use of CLTD/SCL/CLF, was carried through for hour 1600 only, in the manner that it would primarily be applied by users. For comparison purposes, it was also calculated for each of the daily 24 h and that cooling load profile plotted on Figure 5. There is no comparable heat gain profile, as this method does not produce such values directly. The curve peaks at 1700 hours, one hour later than the others, but with a total value 19.8% greater than TFM. The profile is somewhat different from and between those for TFM and TETD/TA during unoccupied hours.

Note: The small building used in these examples is more massive than typical for a similar function in post-1990 construction, and it would probably not meet ASHRAE *Standard* 90.1-1989 energy requirements. Calculating the entire building as a single simultaneous load could certainly be questioned, particularly in any larger configuration; thus, it is used here purely to illustrate the techniques discussed.

GLAZING MATERIALS 27.31
Plastic Materials for Glazing 27.31
Choosing Glass for Buildings 27.32
SHADING 27.33
Exterior Shading 27.33
Indoor Shading Devices 27.35
Visual and Thermal Controls 27.39

FENESTRATION refers to any glazed aperture in the building envelope. Fenestration components include: (1) glazing material, either glass or plastic; (2) framing, mullions, muntins, and dividers; (3) external shading devices; (4) internal shading devices; and (5) integral (between-glass) shading systems.

Fenestration (1) satisfies human needs for visual communication with the outside world; (2) admits solar radiation to provide supplemental daylight and heat, and, in some cases, outside air; (3) provides egress in low-rise buildings in case of fire or other emergencies; and (4) enhances the exterior and interior appearance of a building.

The designer must consider the following factors when selecting fenestration: (1) *architectural*, by identifying design options and their synthesis to achieve energy conservation, including possible use of both electric illumination and daylight, with controls to reduce electric lighting automatically when daylight is available; (2) *thermal*, by designing for heat losses and/or gains and surface temperatures consistent with occupant comfort and energy conservation; (3) *economic*, by evaluating first costs and life-cycle costs of alternative fenestration designs; and (4) *human need*, by determining the psychological desire or physical need for fenestration and the proper illumination standards for projected use of the space and for occupant comfort and acceptance.

This chapter covers the design and evaluation of fenestration based on thermal analysis and energy conservation. When necessary, the information in this chapter should be modified to follow manufacturers' directions for proper use of their products.

Energy Effects of Fenestration

Fenestration affects building energy use through four basic mechanisms—thermal heat transfer, solar heat gains, air leakage, and daylighting. The net effect of a fenestration system on total building energy requirements, including heating, cooling, and lighting energy, depends on (1) the characteristics and orientation of the fenestration, (2) the weather and solar radiation conditions, and (3) the operation of the building thermal system.

Careful design of the fenestration can minimize energy use. In general, the energy impacts of fenestration can be optimized by (1) using daylight to offset lighting requirements, (2) using passive solar heat gain to offset winter space heating, (3) using glazings with special transmission properties to reject excessive solar heat gain, and (4) specifying insulated glazings and low air leakage fenestration designs.

Fenestration Components

Common glazing materials are glass, plastic, and other materials having good light transmittance. Inward or outward heat flow through fenestration by radiation, conduction, or convection can be controlled by various single or multiple (insulating) glazings, by exterior and/or interior shading, and by spectrally selective tints, films, and/or coatings. Sunlight or skylight that is too bright or glaring may be controlled by tinted glazing and by fixed or adjustable exterior or interior shading or both. Tinted glazing and/or draperies of proper openness may be appropriate to modify an unattractive or distracting view. Privacy with a degree of outward view can be obtained only when the illumination level outside is substantially above that inside. For this purpose, reflective or tinted glazing and/or draperies of the correct shade and openness of weave can be used and are effective in the daytime. For privacy at night, nearly opaque materials, as well as slatted blinds or roller shades, are more effective.

Outdoor sounds can be reduced with an airtight building envelope. Additional noise reduction can be achieved by heavier and/or multiple glazing, well sealed around the edges. While draperies of closely woven fabrics are good sound absorbers and help reduce sound within a room, they do not directly reduce outdoor sound coming through fenestration. Glazing materials must not break when under wind loads and thermal stress; they must also meet building codes. Applicable published standards and manufacturers' recommendations should be followed.

CALCULATING FENESTRATION ENERGY FLOW

Energy flows through fenestration via three physical effects: (1) conductive and convective heat transfer between the outer fenestration surface and the adjacent air caused by the temperature difference between that air and the interior space of the building; (2) net long-wave (above 2500 nm) radiative exchange between the outer fenestration surface and the sky, ground, or adjacent objects; and (3) short-wave (below 2500 nm) solar radiation incident on the window, either directly from the sun after scattering in the atmosphere or after reflection from the ground or adjacent objects. Simplified calculations are based on the observation that the temperatures of the sky, ground, and surrounding objects (and hence their radiant heat transfers) correlate with the exterior air temperature. The radiative interchanges are then approximated by assuming that all the radiating surfaces (including the sky) are at the same temperature as the outdoor air. With this assumption, the basic equation for the instantaneous energy flow q through a fenestration is

$$q = U_o A_T (t_{out} - t_{in}) + E_t (A_G F_G + A_{Frm} F_{Frm}) \quad (1)$$

The preparation of this chapter is assigned to TC 4.5, Fenestration.

where

U_o = overall coefficient of heat transfer (U-factor)
t_{in} = interior air temperature
t_{out} = exterior air temperature
A_T = total area of fenestration
A_G = glazing (transparent) area
A_{Frm} = frame (opaque) area
F_G = glazing solar heat gain coefficient
F_{Frm} = frame solar heat gain coefficient
E_t = incident total irradiance

The quantities U_o, F_G, and F_{Frm} are frequently considered constants; however, they slowly vary as functions of the environmental variables, most importantly temperatures and wind speed. The solar heat gain coefficients also depend significantly on solar incident angle.

The principal justification for Equation (1) is its simplicity, achieved by collecting all the linked radiative, conductive, and convective energy transfer processes into *U* and *F*. These quantities vary slowly because (1) convective heat transfer rates vary as fractional powers of temperature differences or free-stream speeds, (2) variations in temperature due to the weather or climate are small on the absolute temperature scale (°R) that controls radiative heat transfer rates, and (3) fenestration systems always involve at least two thermal resistances in series.

OVERALL COEFFICIENT OF HEAT TRANSFER (U-FACTOR)

In the absence of sunlight, air infiltration, and moisture condensation, the first term in Equation (1) represents the rate of thermal heat transfer through a fenestration system. Most systems consist of transparent multipane glazing units and an opaque sash and frame (hereafter called frame). The glazing unit's heat transfer paths include a one-dimensional center-of-glass contribution and a two-dimensional edge contribution. The frame contribution is primarily two-dimensional.

Consequently, the total rate of heat transfer through a fenestration system can be calculated knowing the separate heat transfer contributions of the center glass, edge glass, and frame. (When present, glazing dividers, such as decorative grilles and muntins, also affect heat transfer, and their contribution must be considered). The overall U-factor is estimated using area-weighted U-factors for each contribution by:

$$U_o = (U_{cg}A_{cg} + U_{eg}A_{eg} + U_fA_f)/A_{pf} \qquad (2)$$

where the subscripts *cg*, *eg*, and *f* refer to the center-of-glass, edge-of-glass, and frame, respectively. A_{pf} is the area of the fenestration product's rough opening in the wall or roof less installation clearances. Where a fenestration product has glazed surfaces in only one direction (typical windows), the sum of the areas equals the projected area. Skylights, greenhouse/garden windows, bay/bow windows, etc., because they extend beyond the plane of the wall/roof, have greater surface area for heat loss than that of a window with a similar glazing option and frame material; consequently, U-factors for such products are greater.

Center-of-glass U-factor. Heat flow across the central glazed portion of a multipane unit must consider both convective and radiative transfer in the gas space. Convective heat transfer is estimated based on high aspect-ratio, natural convection correlations for vertical and inclined air layers (ElSherbiney *et al.* 1982, Shewen 1986, Wright 1991). Radiative heat transfer (ignoring gas absorption) is quantified using a more fundamental approach. Rubin (1982) and Hollands and Wright (1982) devised computational methods to solve the combined heat transfer problem.

Values for U_{cg} at standard indoor and outdoor conditions depend on such glazing construction features as the number of glazing panes, the gas-space dimensions, the orientation relative to vertical, the emittance of each surface, and the composition of the fill gas. Several computer programs can be used to estimate glazing unit heat transfer for a wide range of glazing construction (Arasteh *et al.* 1989, Sullivan and Wright 1987). The National Fenestration Rating Council calls for WINDOW 4.0 from Lawrence Berkeley Laboratory (1992) as a standard calculation method.

Figure 1 shows the effect of gas space width on U_{cg} for various glazing units. U-factors are plotted for air, argon, and krypton fill-gases and for high (uncoated) and low (coated) values of surface emittance. Gas space widths greater than 0.5 in. have no significant effect on U_{cg}, but greater glazing unit thicknesses decrease U_o since the length of the shortest heat flow path through the frame increases. A low-emittance coating combined with krypton gas fill significantly reduces heat transfer in narrow gap-width glazing units. The value of U_{cg} for sloped glazings (with heat flow

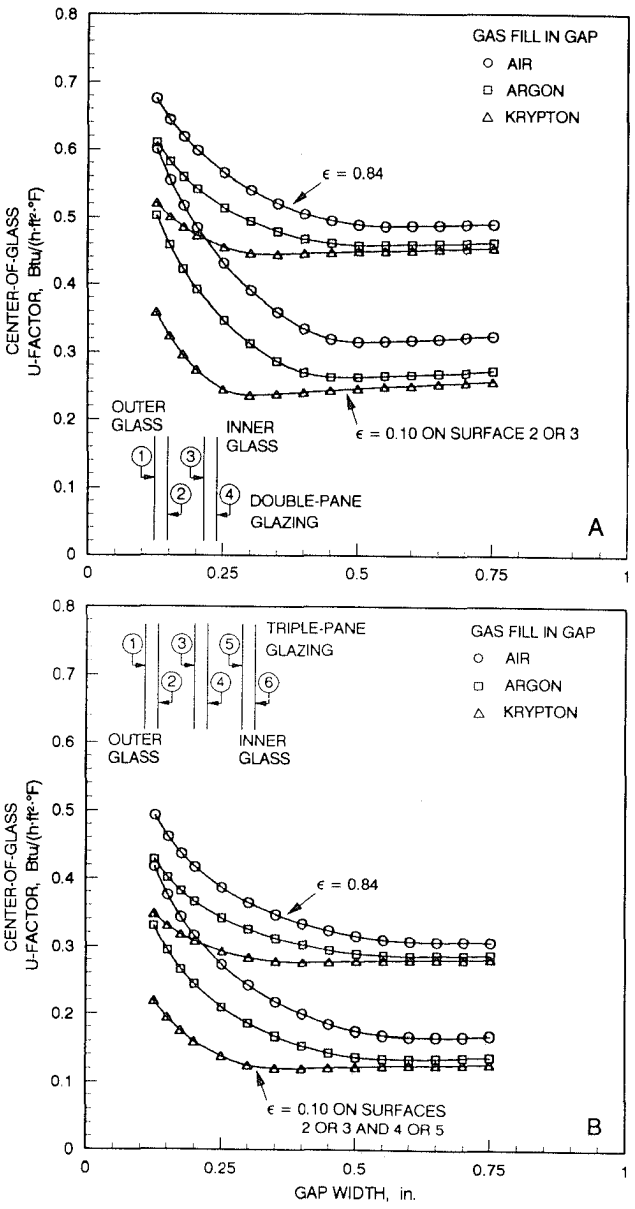

Fig. 1 Center of Glass U-Factor for Vertical Double- and Triple-Pane Glazing Units

up) is greater than that for vertical glazings because both the interior film coefficient and the air space coefficient is larger, particularly with the 0.5 in. gap spacing between glazings.

Edge-of-glass U-factor. Insulating glass units usually have continuous spacer members around the glass perimeter to separate the glazing and provide an edge seal. Aluminum spacers greatly increase conductive heat transfer between the contacted inner and outer glazing, thereby degrading the thermal performance of the glazing unit locally. Laboratory measurements reported by Peterson (1987) showed this conductive region to be limited to a 2.5 inch-wide band around the perimeter of the glazing unit.

Edge-of-glass heat transfer is two-dimensional and requires detailed modeling for accurate determination. Based on detailed two-dimensional modeling, Arasteh (1989) developed the following correlation to calculate the edge-of-glass U-factor as a function of spacer type and center-of-glass U-factor:

$$U_{eg} = A + BU_{cg} + CU_{cg}^2 \quad (3)$$

where A, B, and C are correlation coefficients, which are listed in Table 1 for metal, insulating (including wood) and fused glass spacers, and a combination of insulating and metal spacers. The correlation constants for the combination of metal and insulated spacers were derived from computer simulations, which showed that 85% of the benefit in triple-glazing is attributable to the insulated spacer.

Approximate edge-of-glass U-factors as a function of the center-of-glass U-factor is shown in Figure 2. The spacer edge is assumed to be even with the line of sight of the glazing. Curves are for aluminum spacers with sealants (metallic) and nonmetal (insulating) spacers, including fiberglass, wood, and butyl. Values for glass edges and steel spacers fall between the metallic and insulating spacer curves. This edge effect does not occur with single glazing. For highly insulating glazing, edge heat transfer can significantly increase the overall U-factor. Thus, test data or design-specific computations should account for this effect.

Table 1 Equation (3) Coefficients for Edge-of-Glass U-Factor

	A	B	C
Metal	0.223	0.842	−0.153
Insulating	0.120	0.682	0.244
Glass	0.158	0.774	0.057
Metal + insulation	0.135	0.706	0.187

Note: A, B, and C have units of $[Btu/(h \cdot ft^2 \cdot °F)]^n$, where n = 1, 0, and −1, respectively.

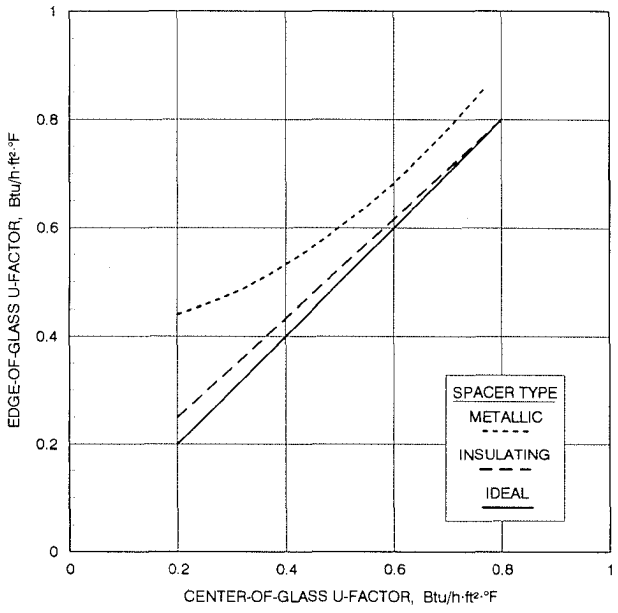

Fig. 2 Relationship between Edge-of-Glass U-Factor and Center-of-Glass U-Factor for Various Spacers

Frame U-factor. Fenestration frame elements consist of all structural members exclusive of the glazing units and include sash, jamb, head, and sill members; meeting rails; mullions; and other glazing dividers. Estimating the rate of heat transfer through the frame is complicated by (1) the variety of fenestration products and frame configurations, (2) the different combinations of materials used for frames, (3) the different sizes available in residential and commercial applications, and to a lesser extent, (4) the glazing unit width and spacer type. Internal dividers or grilles have little impact on the fenestration U-factor, provided there is at least a 1/8-in. gap between the divider and each panel of glass.

Fenestration product type (or operator type) refers to the design configuration (*e.g.*, casement, slider, or fixed window, patio door, skylight, etc.). Materials commonly used for framing members include wood, aluminum, and vinyl. Fiberglass-framed windows are also available. Manufacturers sometimes combine these materials as clad units, (*e.g.*, vinyl-clad aluminum, aluminum-clad wood) to increase durability or improve aesthetics. Aluminum units are available in both solid metal and in "thermally broken" units with plastic inserts that reduce the conductive heat transfer through framing members. Vinyl-framed units may also be structurally reinforced with steel rods and/or may have interior cavities filled with foam insulating materials.

Computer simulations found that frame heat loss in most fenestration is controlled by a single component or controlling resistance, and only changes in this component significantly affect frame heat loss (Enermodal Engineering 1990). For example, the frame U-factor for thermally broken aluminum windows is largely controlled by the depth of the thermal break material in the heat flow direction. For aluminum frames without a thermal break, the inside film coefficient provides most of the resistance to heat flow. For vinyl- and wood-framed fenestrations, the controlling resistance is the shortest distance between the inside and outside surfaces, which usually depends on the thickness of the sealed glazing unit.

Carpenter and McGowan (1993) experimentally validated frame U-factors for a variety of fixed and operable window types, sizes, and materials using computer modelling techniques. Table 2 lists frame U-factors for a variety of frame and spacer materials and glazing unit thicknesses.

Interior and exterior surface coefficients. Part of the overall thermal resistance of a fenestration system is due to the convective and radiative heat transfer between the exposed surfaces and the environment. Surface heat transfer coefficients at the outer and inner glazing surfaces, h_o and h_i, respectively, combine the effects of radiation and convection.

The wind speed and orientation of the building are important in determining h_o. This relationship has long been studied and many correlations have been proposed for h_o as a function of wind speed. However, no universal relationship has been accepted, and limited field measurements at low air speeds by Klems (1989) show significant difference with values used by others.

Convective heat transfer coefficients are usually determined at standard temperature and air velocity conditions on each side. Wind speed can vary from less than 50 fpm for calm weather, free convection conditions, to over 25 mph for storm conditions. A standard value of 5.1 $Btu/h \cdot ft^2 \cdot °F$ corresponding to a 15 mph is often used to represent winter design conditions. At near-zero

$h_i = h_c + h_r = A(\Delta t)^{0.25} + [e_g \sigma (T_g^4 - T_i^4)]/(T_g - T_i)$ where $A = 0.27$.

wind speed, h_o varies with outside air and surface temperature, orientation to vertical, and air moisture content.

For natural convection at the inner surface of a vertical window, the inner surface coefficient depends on the indoor air and glass surface temperatures and on the emittance of the glass inner surface. Table 3 shows the variation of h_i for winter (t_i = 70°F) and summer (t_i = 75°F) design conditions. Designers often use h_i = 1.46 Btu/h · ft² · °F, which corresponds to t_i = 70°F, glass temperature = 20°F, and uncoated glass with e_g = 0.84. For summer conditions, the conventional h_i = 1.46 Btu/h · ft² °F corresponds approximately to glass temperature = 90°F and t_i = 75°F.

Heat transfer between the glazing surface and its environment is driven not only by the local air temperatures but also by the radiant temperatures to which the surface is exposed. The radiant temperature of the indoor environment is generally assumed to be equal to the indoor air temperature. While this is a safe assumption where a small window is exposed to a large room with surface temperatures equal to the air temperature, it is not valid in rooms where the window is exposed to other large areas of glazing surfaces (*e.g.*, greenhouse, atrium) or to other cooled or heated surfaces (Parmelee 1947).

The radiant temperature of the outdoor environment is frequently assumed to be equal to the outdoor air temperature. This assumption may be in error, since additional radiative heat loss occurs between a fenestration and the clear sky (Duffie and Beckman 1980). Therefore, for clear sky conditions, some effective outdoor temperature $t_{o,e}$ should replace t_o, in Equation (1). For methods for determining $t_{o,e}$ see, for example, work by the University of Waterloo (1987). Note that a fully cloudy sky is assumed in ASHRAE design conditions.

Especially for single glass, U-factors depend strongly on interior and exterior film coefficients. The U-factor for single glass (neglecting the glass resistance) is:

$$U_{cg} = h_o h_i/(h_o + h_i) \quad (4)$$

Values for h_i presented in Table 3 can result in values of U_{cg} for single glass to range from more than 1.4 Btu/h · ft² · °F in winter for an internally coated glass with a low-emittance film to approximately 1.0 Btu/h · ft² · °F in summer for an uncoated clear glass, and 1.2 Btu/h · ft² · °F with bright sunshine.

The air space in an insulating glass panel made up of glass with no reflective coating on the air space surface has a coefficient h_S is given in Table 4 for an effective emittance of 0.72. When a reflective coating is applied to the air space surface, h_S can be selected from Table 4 by first calculating the effective air space emittance E by Equation (5).

$$E = 1/(1/e_o + 1/e_i - 1) \quad (5)$$

where e_o and e_i are the hemispherical emittances of the two air space surfaces. Hemispherical emittance of ordinary uncoated glass is 0.84 over a wavelength range of 0.4 to 40 μm.

Representative U-factors for fenestration systems. Table 5 lists computed U-factors at winter design conditions for many currently available designs. The table is based on ASHRAE-sponsored research involving laboratory testing and computer simulation of various fenestration products. Values are listed for vertical installation and for skylights that are sloped 20° from the horizontal. When available, test data may provide more accurate results for specific products. However, a wide range of measured U-factors for similar products has been reported (Hogan 1988). Different test methods sometimes give different U-factors (McCabe *et al.* 1986), but the procedures presented in NFRC *Standard* 100-91 or CSA *Standard* A440.2 are generally accepted. Fenestration should be rated in accordance with these standards, while Table 5 can be used as an estimating tool in the early phases of design.

Data are based on center-of-glass and edge-of-glass component U-factors and assume that there are no dividers. If product-specific information is not available from the NFRC or CSA standards programs, the overall U-factors in Table 5 are appropriate

Adapted from Building Materials and Structures, Report 151, United States Dept. of Commerce.

for calculating compliance with the requirements of ASHRAE *Standard* 90. However, they apply only to the specific design conditions described in the footnotes in the table, and they are typically used only to determine peak load conditions for sizing heating equipment.

While these U-factors have been determined for winter conditions, they can also be used to estimate heat gain during peak cooling conditions, since conductive gain, which is one of several variables, is usually a small portion of the total heat gain for fenestration in direct sunlight. Glazing designs and framing materials may be compared in choosing a fenestration system that needs a specific winter design U-factor.

The multiple glazing categories are appropriate for sealed glass units and the addition of storm sash to other glazing units. No distinction is made between flat and domed units such as skylights. For acrylic domes, use an average gas-space width to determine the U-factor. Note that skylight U-factors are greater than those of other similar products. While this is partially due to the difference in slope, it is largely because the skylight surface area, which includes the curb, can vary from 13 to 240% greater than the rough opening area depending on the size and mounting method. Unless noted, all multiple-glazed units are filled with dry air. Argon units are filled with 100% argon. U-factors for CO_2 filled units are similar to argon fills. For spaces up to 0.5 in., argon/SF_6 mixtures with up to 70% SF_6 are generally the same as argon fills. Krypton gas can provide U-factors lower than those for argon for glazing spaces less than 0.5 in.

Table 5 provides data for four values of hemispherical emittance and for 0.25 and 0.5 in. gas space width. The emittance of various low-emittance glasses varies considerably between manufacturers and processes. When the emittance is between the listed values, interpolation may be used. When manufacturers' data are not available, assume that glass with a pyrolytic (hard) coating has an emittance of 0.40, and that glass with a sputtered (soft) coating has an emittance of 0.10. Some coated glazings have lower emittance values. Tinted glass does not change the winter U-factor. Also, some reflective glass may have an emittance less than 0.84. Nonlinear interpolation for gas space width should be based on the equation in footnote 5.

Frame type refers to the primary unit. Thus, when storm sash is added over another glazing, use the values for a nonstorm frame. For glazing with a steel frame, use aluminum frame values. For vertical sliders, horizontal sliders, casement, awning, and pivoted and dual-action windows, use the operable category. Fixed windows can also represent glazed wall systems. Double-door U-factors can also represent single glass doors.

The U-factors in Table 5 are based on the definitions of the four product types, nominal frame sizes, and proportion of frame to glass area as shown in Figure 3. The nominal dimensions for skylights (NFRC size AA) correspond to centerline spacings of roof framing members; consequently, the rough opening dimensions are 22.5 in. by 46.5 in. The skylight coefficients assume the presence of an uninsulated 4 in. curb (either integral to the skylight or field installed). Skylights with smaller curbs, insulated curbs, or no curbs would have lower U-factors.

To estimate the overall U-factor of a fenestration product that differs significantly from the assumptions given in Table 5 and/or Figure 3, first determine the percentage area that is frame/sash, center-of-glass, and edge-of-glass (based on a 2.5 in. band around the perimeter of each glazing unit). Next, determine the appropriate component U-factors. These can be taken either from the standard values listed in italics in Table 5 for glass, the values in Table 2 for frames, or from some other source such as test data or computed factors. Finally, multiply the percent area and the component U-factors, and sum these products to obtain the overall U-factor U_o.

Notes for Table 5

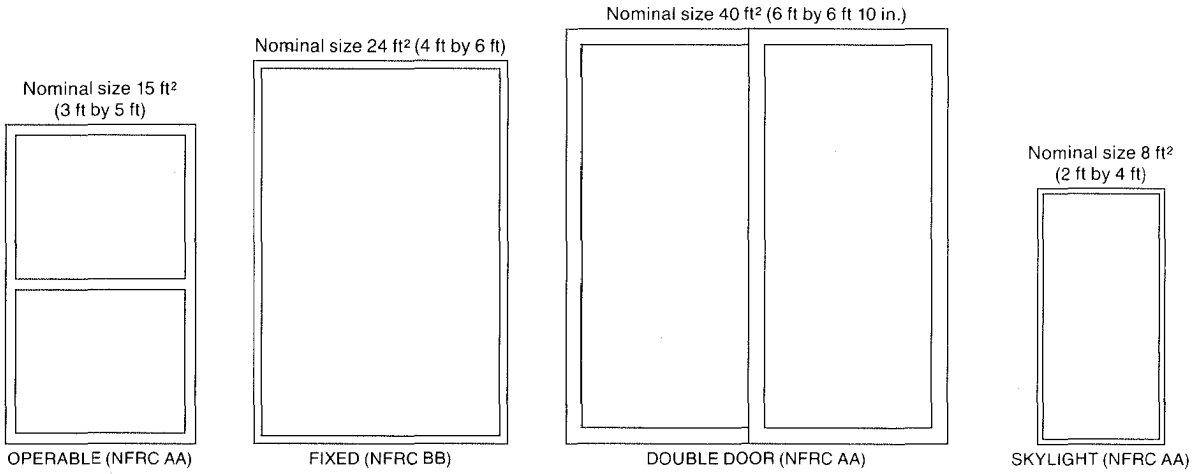
1. All heat transmission coefficients in this table include film resistances and are based on winter conditions of 0°F outdoor air and 70°F indoor air temperature, with 15 mph outdoor air velocity and zero solar flux. With the exception of single glazing, small changes in the interior and exterior temperatures will not significantly affect overall U-factors. The coefficients are for vertical position except skylight values, which are for 20° from horizontal with heat flow up.
2. Glazing layer surfaces are numbered from the outside to the inside. Double, triple, and quadruple refer to the number of glazing panels. All data are based on 1/8 in. glass, unless otherwise noted. Thermal conductivities are: 0.53 Btu/(h · ft · °F) for glass, and 0.11 Btu/(h · ft · °F) for acrylic and polycarbonate .
3. Standard spacers are metal. Insulation means wood, fiberglass, or butyl. Edge-of-glass effects assumed to extend over the 2-1/2 in. band around perimeter of each glazing unit as seen in Figure 3.
4. Product sizes are described in Figure 3 and frame U-factors are from Table 2.
5. Interpolation procedure for estimating U_{cg} for vertically oriented gas space widths between 0.25 and 0.5 in. The most general equation is:

$$U_t = \left[\frac{1}{U_{1/4}} - \frac{n_g}{h + 48k_g} + \frac{n_g}{h + (12k_g/l)}\right]^{-1}$$

$$h = -36k_g + \left[\frac{24n_g k_g U_{1/4} U_{1/2}}{U_{1/4} - U_{1/2}} + 144k_g^2\right]^{0.5}$$

where

n_g = number of gaps (*e.g.*, double-pane windows have one gap)
k_g = gas conductivity Btu/(h · ft · °F)
l = gas space width of window, in.
$U_{1/4}$ = U-factor for identical glazing with 1/4 in. gas spaces
$U_{1/2}$ = U-factor for identical glazing with 1/2 in. gas spaces



Nominal size 15 ft²
(3 ft by 5 ft)
Nominal size 24 ft² (4 ft by 6 ft)
Nominal size 40 ft² (6 ft by 6 ft 10 in.)

OPERABLE (NFRC AA)
FIXED (NFRC BB)
DOUBLE DOOR (NFRC AA)
SKYLIGHT (NFRC AA)

Frame Material	Frame Width, in. Operable	Fixed	Double Door	Skylight
Aluminum without thermal break	1.5	1.3	2.1	0.7
Aluminum with thermal break	2.8	1.3	2.6	0.7
Aluminum clad wood/reinforcing vinyl	2.8	1.6	3.8	0.9
Wood/vinyl	2.8	1.6	3.5	0.9
Fiberglass	3.1	1.8	4.0	n/a

Fig. 3 Standard Fenestration Units

Example 1. Estimate the U-factor for a fixed window (NFRC Size BB) with a reinforced vinyl frame and double-glazing with a sputter-type low-e coating (e = 0.10). The gap is 0.5 in. wide and argon-filled and the spacer is metal.

Solution: Locate the glazing system type in the first column of Table 5 (ID = 20). Then, find the appropriate frame type (reinforced vinyl), operator type (fixed), and spacer type (metal). The U-factor listed (in the third column on the facing page) is 0.32.

Example 2. Estimate a representative U-factor for a wood-framed, 38 in. by 82 in. swinging French door with eight 11-in. by 16-in. panes (true divided panels), each consisting of clear double-glazing with a 0.5 in. air space.

Solution: Without more detailed information, assume that the dividers have the same U-factor as the frame, and that the divider edge has the same U-factor as the edge-of-glass. Calculate the center-of-glass, edge-of-glass, and frame areas.

$$A_{cg} = 8[(11 - 5)(16 - 5)] = 528 \text{ in}^2$$

$$A_{eg} = 8(11 \times 16) - 528 = 880 \text{ in}^2$$

$$A_f = (38 \times 82) - 8(11 \times 16) = 1708 \text{ in}^2$$

Select the center-of-glass, edge-of-glass, and frame U-factors. These component U-factors are 0.49 and 0.60 (from Table 5, glazing ID = 6, columns 1 and 2) and 0.49 (from Table 2, wood frame double door, double-glazing) Btu/h · ft² · °F, respectively.

$$U_o = [(0.49 \times 528) + (0.60 \times 880) + (0.49 \times 1708)]/(38 \times 82) = 0.52 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}.$$

Example 3. Estimate the U-factor for a 60 in. by 36 in. aluminum framed garden window (NFRC Size AA) that projects out 12 in. from the wall surface. The glazing is double-glass with a 0.25 in. air space and a metal spacer. All of the glazing is fixed (*i.e.*, nonoperable) and the frame is 1 in. wide. The base is 0.75 in. plywood.

Solution: The U-factor is determined by calculating the heat flow through all five surfaces (front, two sides, top, and bottom) and then dividing by the projected area of the window (*i.e.*, the 60 in. by 36 in. opening in the insulated wall).

The U-factors are 0.57 Btu/h · ft² · °F for the center-of-glass and 0.65 Btu/h · ft² · °F for the edge-of-glass (from Table 5, glazing ID = 5, columns 1 and 2) and 1.78 Btu/h · ft² · °F (from Table 2, aluminum frame, fixed window, double-glazing), respectively.

From Table 4 in Chapter 22, the resistance of 0.75 in. plywood is 0.93 h · ft² · °F/Btu. When the exterior film resistance of 0.17 and interior downward flow film resistance of 0.92 h · ft² · °F/Btu (from Table 1, Chapter 22) are added, the total resistance is 2.02 h · ft² · °F/Btu and the

U-factor is 1/2.02 = 0.50 Btu/h·ft²·°F. (The glazing U-factors in Table 5 already include the film resistances.) Now calculate the areas.

For the front surface:

$$A_{cg} = 53 \times 29 = 1537 \text{ in}^2$$

$$A_{eg} = (58 \times 34) - (53 \times 29) = 435 \text{ in}^2$$

$$A_f = (60 \times 36) - (58 \times 34) = 188 \text{ in}^2$$

For the two sides:

$$A_{cg} = 2(5 \times 29) = 290 \text{ in}^2$$

$$A_{eg} = 2[(10 \times 34) - (5 \times 29)] = 390 \text{ in}^2$$

$$A_f = 2[(12 \times 36) - (10 \times 34)] = 184 \text{ in}^2$$

For the top surface:

$$A_{cg} = 53 \times 5 = 265 \text{ in}^2$$

$$A_{eg} = (58 \times 10) - (53 \times 5) = 315 \text{ in}^2$$

$$A_f = (60 \times 12) - (58 \times 10) = 140 \text{ in}^2$$

For the bottom surface,

$$A_{plywood} = 58 \times 10 = 580 \text{ in}^2$$

$$A_f = (60 \times 12) - (58 \times 10) = 140 \text{ in}^2$$

Then calculate the U-factor as follows:

$$U_o = [0.57(1537 + 290 + 265) + 0.65(435 + 390 + 315) + 1.78(188 + 184 + 140 + 140) + (0.50 \times 580)]/(60 \times 36)$$
$$= 1.57 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

Note that the U-factor for this garden window is even greater than that for a skylight with the same type of glazing. While both have a surface area that is approximately twice the rough opening area, the skylight curbs are often wood, but the garden window side and top panels are glazed.

Example 4. Find the center-of-glass U-factor for a triple-pane window with 0.375 in. air-filled gaps and a low-e coating ($e = 0.2$) on the fifth surface.

Solution: From Table 5, for 0.25 in. spacing, $U_{1/4} = 0.33$ and for 0.5 in. spacing, $U_{1/2} = 0.24$. The thermal conductivity of air is 0.014 Btu/h·ft·°F. Using the equation in footnote 5,

$$h = -36 \times 0.014 + \left[\frac{24 \times 2 \times 0.014 \times 0.33 \times 0.24}{(0.33 - 0.24)} + 144 \times 0.014^2\right]^{0.5} = 0.283$$

$$U_{3/8} = \left[\frac{1}{0.33} - \frac{2}{0.283 + 48 \times 0.014} + \frac{2}{0.283 + (12 \times 0.014/0.375)}\right]^{-1}$$
$$= 0.27 \text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F}$$

Because of the combined effects of solar gain, wind, ambient temperature and cloud cover, fenestration performance is likely to be different from the data in Table 5 when products are installed in buildings. Since these factors influence the rate of heat transfer through fenestration, seasonal or annual energy flows cannot be accurately determined solely on the basis of the design-day U-factors. Where U-factors are to be compared at different wind speeds, Table 6 provides approximate data to convert the overall U-factor data at one specific wind condition to a U-factor at another. Performance data in Table 5 are based on the assumption of an overcast sky, which implies that the effective sky temperature for radiative heat transfer is equal to the outdoor air temperature. This assumption gives reasonable results with 7.5- and 15-mph wind speeds; however, with a clear sky and nearly still wind conditions, significant heat transfer occurs by radiation, and the data in Table 6 may underestimate the actual U-factor.

Table 6 Glazing U-Factor for Various Wind Speeds

Wind speed, mph

DETERMINING INCIDENT SOLAR FLUX

Solar Radiation

The flux of solar radiation on a surface normal to the sun's rays beyond the earth's atmosphere at the mean earth-sun distance (92.9×10^6 miles) is defined as the solar constant E_{sc}. The currently accepted value is 433.34 Btu/h·ft² (CIMO 1982). Because the earth's orbit is slightly elliptical, the extraterrestrial radiant flux E_o varies from a maximum of 448.2 Btu/h·ft² on January 3, when the earth is closest to the sun, to a minimum of 419.2 Btu/h·ft² on July 4, when the earth-sun distance reaches its maximum.

The earth's orbital velocity also varies throughout the year, so *apparent solar time*, as determined by a sundial, varies slightly from the *mean time* kept by a clock running at a uniform rate. This variation, called the *equation of time*, is given in Table 7. The sun's position in the sky is determined by *local solar time*, found by adding the equation of time to the local civil time. *Local civil time* is found by adding to or subtracting from *local standard time* (LST) the longitude correction of 4 minutes per degree difference between the local longitude and the longitude of the standard time meridian for that locality. In the United States and Canada, these values are 60° for Atlantic Standard Time (ST); 75° for Eastern ST; 90° for Central ST; 105° for Mountain ST; 120° for Pacific ST, 135° for Yukon ST; 150° for Alaska-Hawaii ST.

Table 7 Extraterrestrial Solar Radiation Intensity and Related Data

	I_o Btu/(h·ft²)	Equation of Time, min.	Declination, degrees	A Btu/(h·ft²)	B (Dimensionless Ratios)	C (Dimensionless Ratios)

Nov	445.3	13.8	−19.8	387	0.149	0.063
Dec	449.1	1.6	−23.45	391	0.142	0.057

Note: Data are for 21st day of each month during the base year of 1964.

Equation (6) relates Apparent Solar Time (AST) to Local Standard Time (LST) as follows:

$$AST = LST + ET + 4(LSM - LON) \quad (6)$$

where

ET = equation of time, minutes of time
LSM = local standard time meridian, ° of arc
LON = local longitude, ° of arc
4 = minutes of time required for 1.0 degree rotation of earth

Because the earth's equatorial plane is tilted at an angle of 23.45° to the orbital plane, the solar declination δ (the angle between the earth-sun line and the equatorial plane) varies throughout the year, as shown in Figure 4 and Table 7. This variation causes the changing seasons, with their unequal periods of daylight and darkness.

The spectral distribution of solar radiation beyond the earth's atmosphere (Figure 5) resembles the radiant energy emitted by a blackbody at about 10,800°F. The invisible ultraviolet region with wavelengths between 0.29 and 0.40 μm contains about 7% of the total energy, while the visible region between 0.4 and 0.7 μm contains 39%, and the near infrared region between 0.7 and 3.5 μm contains the remaining 52%. The peak intensity, about 700 Btu/h·ft²·μm, is reached at about 0.45 μm in the green portion of the visible spectrum.

In passing through the earth's atmosphere, the sun's radiation is reflected, scattered, and absorbed by dust, gas molecules, ozone, water vapor, and water droplets (clouds). The extent of this depletion at any given time is determined by atmospheric composition and length of the atmospheric path traversed by the sun's rays. This length is expressed in terms of the air mass m, the ratio of the mass of atmosphere in the actual earth-sun path to the mass which would exist if the sun were directly overhead at sea level (m = 1.0). For most purposes, the air mass at any time equals the cosecant of the solar altitude, multiplied by the ratio of the existing barometric pressure to standard pressure. Beyond the atmosphere, m = 0.

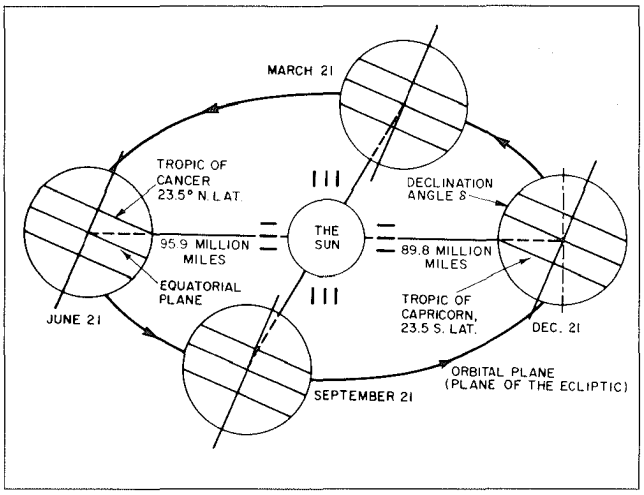

Fig. 4 Motion of Earth around Sun

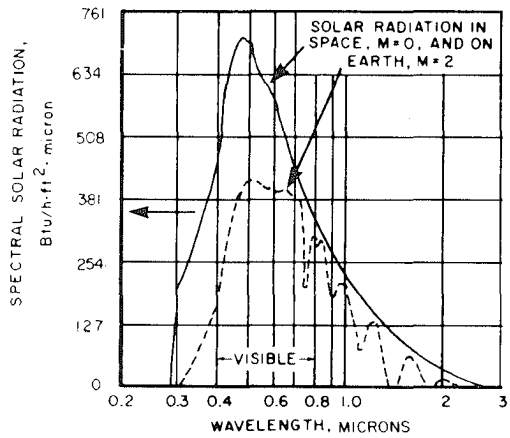

Fig. 5 Extraterrestrial and Terrestrial Solar Radiation

Most ultraviolet solar radiation is absorbed by the ozone in the upper atmosphere, while part of the radiation in the shortwave portion of the spectrum is scattered by air molecules, imparting the blue color to the sky. Water vapor in the lower atmosphere causes the characteristic absorption bands observed in the solar spectrum at sea level (Figure 5). For a solar altitude of 41.8° (air mass = 1.5), the spectrum of the sun's direct radiation on a clear day at sea level shows less than 3% of the total energy in the ultraviolet, 38% in the visible region, and the remaining 59% in the infrared (ASTM 1987). The maximum intensity occurs at 0.50 μm, and virtually no solar energy exists at wavelengths beyond 2.2 μm.

The spectral distributions shown in Part A, Figure 5 for m = 0 and m = 2.0 are adapted from Moon (1940), whose solar radiation data took no account of monthly variations in intensity caused by changes in the earth-sun distance and by the atmosphere's varying average moisture content. Moon used a solar constant of about 420 Btu/h·ft², while the presently recommended value is 433.3 Btu/h·ft². The solar heat gain factors (SHGF) in Tables 12 through 18 are based on terrestrial measurements (Threlkeld and Jordan 1958) and are not affected directly by the change in the accepted value of the solar constant. However, these calculations may be affected by the accuracy of the calculated solar irradiance incident on the glazing. Iqbal (1983), Galanis and Chatiguy (1986), and Gueymard (1993) discuss the accuracy and universality of the radiation model used to produce these data and propose possible improvements.

For many years the glazing industry has used Moon's spectrum (air mass = 2) to obtain spectrally average optical characteristics of glazings. The National Fenestration Rating Council recommends a spectrum at a standard air mass of 1.5 as described in ASTM *Standard* E 891 (1987a). This difference in reference spectrum may result in slight deviations of the solar heat gain coefficient of spectrally selective glazings, whereas the visible transmittance of all types of glazings should remain unchanged.

Some short-wave radiation scattered by air molecules and dust reaches the earth in the form of diffuse radiation E_d. Since this diffuse radiation comes from all parts of the sky, its intensity is difficult to predict and varies as moisture and dust content of the atmosphere change throughout any given day. On a completely overcast day, the diffuse component accounts for all solar radiation reaching the ground.

Some energy absorbed by carbon dioxide and water vapor in the sky reaches the earth in the form of long-wave atmospheric radiation. Because the apparent emittance of the atmosphere depends primarily on its water vapor content (Parmelee and Aubele 1952, Bliss 1961) and is always less than 1.00, usually long-wave radiant energy flows from terrestrial surfaces.

The total short-wave irradiance E_t reaching a terrestrial surface is the sum of the direct solar radiation E_D, the diffuse sky radiation E_d, and the solar radiation reflected from surrounding surfaces E_r. The irradiance of the direct component is the product of the direct normal irradiation E_{DN} and the cosine of the angle of incidence θ between the incoming solar rays and a line normal (perpendicular) to the surface:

$$E_t = E_{DN} \cos \theta_V + E_d + E_r \quad (7)$$

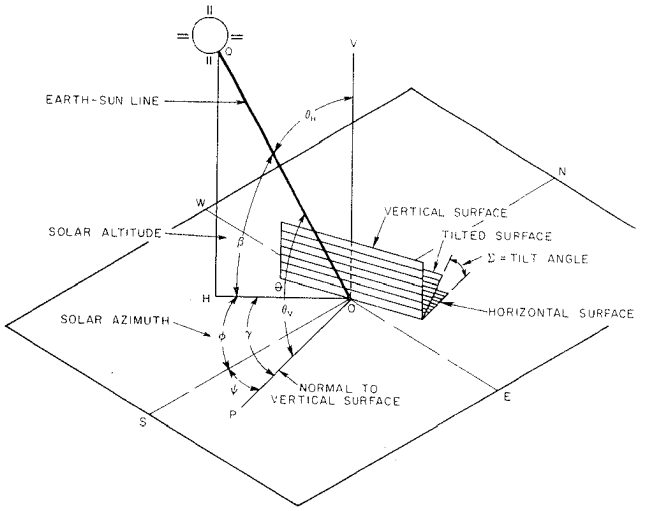

Fig. 6 Solar Angles for Vertical and Horizontal Surfaces

A method of computing all the factors on the right side of Equation (7) follows. Perez *et al.* (1986) give a more detailed model for E_t, which separates the diffuse sky radiation into three components.

Solar Angle Determination

The sun's position in the sky is conveniently expressed in terms of the solar altitude β above the horizontal and the solar azimuth ϕ measured from the south (Figure 6). These angles, in turn, depend on the local latitude L; the solar declination δ, which is a function of the date (Table 7); and the apparent solar time, expressed as the hour angle H, where $H = 0.25$ (number of minutes from local solar noon), in degrees.

Equations (8a) and (8b) relate β and ϕ to the three angles just mentioned:

$$\sin\beta = \cos L \cos\delta \cos H + \sin L \sin\delta \tag{8a}$$

$$\cos\phi = (\sin\beta \sin L - \sin\delta)/(\cos\beta \cos L) \tag{8b}$$

Figure 6 shows the solar position angles and incident angles for horizontal and vertical surfaces. Line OQ leads to the sun, the north-south line is NOS, and the east-west line is EOW. Line OV is perpendicular to the horizontal plane in which the solar azimuth, angle HOS, and the surface azimuth, angle POS (ψ) are located. Angle HOP is the surface solar azimuth defined as:

$$\gamma = \phi - \psi \tag{9}$$

The solar azimuth ϕ is positive for afternoon hours and negative for morning hours. Likewise, surfaces that face west have a positive surface azimuth ψ; those facing east, have a negative surface azimuth (Table 8). If γ is greater than 90° or less than 270°, the surface is in the shade. Table 8 gives values in degrees for the surface azimuth ψ, applicable to the orientations of interest.

The angle of incidence θ for any surface is defined as the angle between the incoming solar rays and a line normal to that surface. For the horizontal surface shown in Figure 6, the incident angle θ_H is QOV; for the vertical surface, the incident angle θ_V is QOP.

Table 8 Surface Orientations and Azimuths, Measured from South

Orientation	N	NE	E	SE	S	SW	W	NW
Surface azimuth, ψ	180°	−135°	−90°	−45°	0	45°	90°	135°

For any surface, the incident angle θ is related to β, γ and the tilt angle of the surface Σ by:

$$\cos\theta = \cos\beta \cos\gamma \sin\Sigma + \sin\beta \cos\Sigma \tag{10}$$

where Σ = tilt angle of surface from horizontal.

When the surface is horizontal, $\Sigma = 0°$, and

$$\cos\theta_H = \sin\beta \tag{11a}$$

For a vertical surface, $\Sigma = 90°$, and

$$\cos\theta_V = \cos\beta \cos\gamma \tag{11b}$$

Example 5. Find the solar azimuth and altitude at 0830 central time on October 21 at 32° north latitude and 95° west longitude.

Solution: Local time is 0830 + 4 (90 − 95) = 0810. The equation of time (Table 7) is +15 min, so apparent solar time (AST) = 0810 + 15 = 0825, or 215 min. before noon, and H = 0.25 × 215 = 53.8°. Table 7 gives the solar declination on October 21 as −10.5°.

Thus, by Equation (8a):

$$\sin\beta = \cos(32)\cos(-10.5)\cos(53.8) + \sin(32)\sin(-10.5) = 0.396$$

$$\beta = 23.3°$$

Using Equation (8b):

$$\cos\phi = \frac{\sin(23.3)\sin(32) - \sin(-10.5)}{\cos(23.3)\cos(32)} = 0.503$$

$$\phi = 59.8°$$

Example 6. For the conditions of Example 5, find the incident angle at a window facing southeast.

Solution: Since the solar azimuth ϕ is to the east (AST < 1200) and the surface azimuth ψ is to the east (Table 8), they are both negative—$\phi = -59.8$, $\psi = -45.0$.

$$\gamma = -59.8 - (-45.0) = -14.8°$$

A negative surface-solar azimuth γ indicates that the sun is east of the normal to the surface. Thus, using Equation (11b)

$$\cos\theta_V = \cos 23.3 \cos(-14.8) = 0.888$$

$$\theta_V = 27.4°$$

Direct Normal Irradiance

At the earth's surface on a clear day, direct normal irradiation, or solar intensity E_{DN} is represented by

$$E_{DN} = A/[\exp(B/\sin\beta)] \tag{12}$$

where

A = apparent solar irradiation at air mass $m = 0$ (Table 7)
B = atmospheric extinction coefficient (Table 7)

(Values of E_{DN} based on these data are given in Tables 13 through 19 for the daylight hours of the 21st day of each month, for latitudes 16 to 64° North in 8° increments.)

Values of A and B vary during the year because of seasonal changes in the dust and water vapor content of the atmosphere and because of the changing earth-sun distance. Equation (12) does not give the maximum value of E_{DN} that can occur in each month, but yields values that are representative of conditions on cloudless days for a relatively dry and clear atmosphere. For very clear atmospheres, E_{DN} can be 15% higher than indicated by Equation (12), using values of A and B in Table 7.

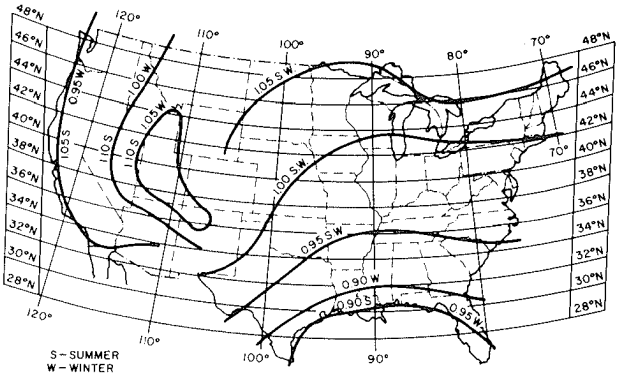

Fig. 7 Estimated Atmospheric Clearness Numbers in United States for Nonindustrial Localities

For locations where clear, dry skies predominate (*e.g.*, at high elevations), or, conversely, where hazy and humid conditions are frequent, values found by using Equation (12) and Table 7 should be multiplied by the Clearness Numbers in Threlkeld and Jordan (1958), reproduced here as Figure 7.

Example 7. Find the direct component of the solar irradiation on a horizontal roof for the conditions of Example 5.

Solution: From Example 5, $\sin\beta = 0.396$, and from Table 7, $A = 378$ Btu/h·ft^2 and $B = 0.160$. Therefore,

$$E_{DN} = 378/[\exp(0.160/0.396)] = 252 \text{ Btu/h} \cdot \text{ft}^2$$

$$E_{DH} = E_{DN} \sin\beta = 252 \times 0.396 = 100 \text{ Btu/h} \cdot \text{ft}^2$$

OPTICAL PROPERTIES

Solar radiation (including both direct rays from the sun and diffuse rays from the sky, clouds, and surrounding objects) incident on a fenestration system is partly transmitted and partly reflected by the glazings of that system. An additional fraction is absorbed within the glazings or the coatings on their surfaces. The fraction of incident flux that is reflected is called the reflectance ρ, the fraction absorbed is called the absorptance α, and the fraction transmitted is the transmittance τ. The sum of the transmittance τ, absorptance α, reflectance ρ of a glazing layer is unity:

$$\tau + \alpha + \rho = 1 \tag{13}$$

However, this is complicated by the fact that radiation incident on a surface can have nonconstant distributions over the directions of incidence and over the wavelength (or frequency) scale. Thus, when measuring one or more of the optical properties, the wavelength distribution and direction of incident radiation must be specified.

The emittance of the surface ϵ is the ratio of the emission of thermal radiant flux from a surface to the flux that would be emitted by a blackbody emitter at the same temperature. Given the temperature and spectral emittance of a surface, the emitted irradiance spectrum can be computed.

Angular Dependence

The concept of solid angle is needed to understand angle dependence. A solid angle is a surface formed by all rays joining a point to a closed curve (Figure 8). For a sphere of radius R, the solid angle is the ratio of the projected area A on the sphere to the square of R. A sphere has a solid angle of 4π steradians (4π sr); a hemisphere has a 2π sr solid angle.

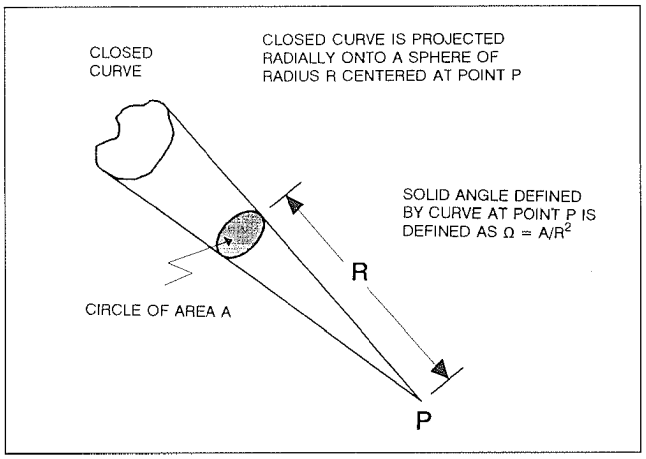

Fig. 8 Geometry for Definition of Solid Angle

Radiation incident on a point in a surface comes to that point from many directions in a conical solid angle. For a cone of half angle α, the solid angle defined by the circular top and point bottom of that cone is given by

$$\Omega = 2\pi(1 - \cos\alpha) \tag{14}$$

In measuring transmittance or reflectance, a sample is illuminated over a specified solid angle. The reflected or transmitted flux is then collected within another solid angle. The size of a conical solid angle and the direction of its axis need to be specified to obtain meaningful results. A conical solid angle is in the shape of a right circular cone.

ASTM *Standards* E 903-82, E 1084-86, E 971-88, and E 972-88 and ASHRAE *Standard* 74-88 on solar optical properties refer to conical-hemispherical measurements because, for most thermal or HVAC calculations, only the total transmitted irradiance due to the direct solar beam is of interest, since all transmitted solar irradiance is considered heat gain.

For complex fenestrations, for daylighting applications, and for some passive solar heating applications, a biconical definition as shown in Figure 9 is needed. This definition is used: (1) to treat sky and direct beam radiation, (2) to handle the directional distribution of the flux entering the room through the window, and (3) to calculate the angle-dependent optical and solar gain properties of multipane window and shade systems.

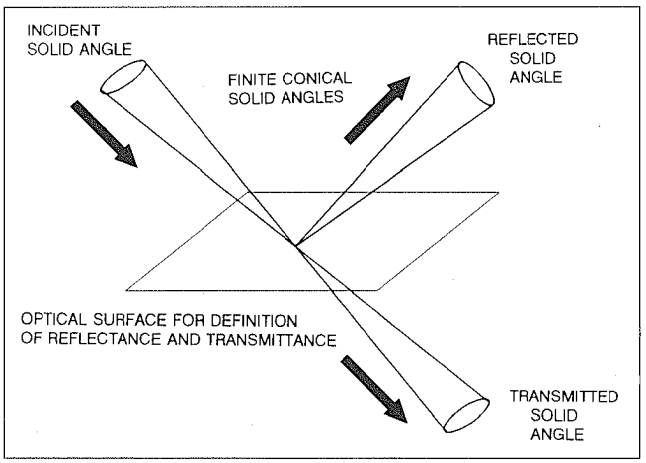

Fig. 9 Geometry for Definition of Biconical Transmittance and Reflectance

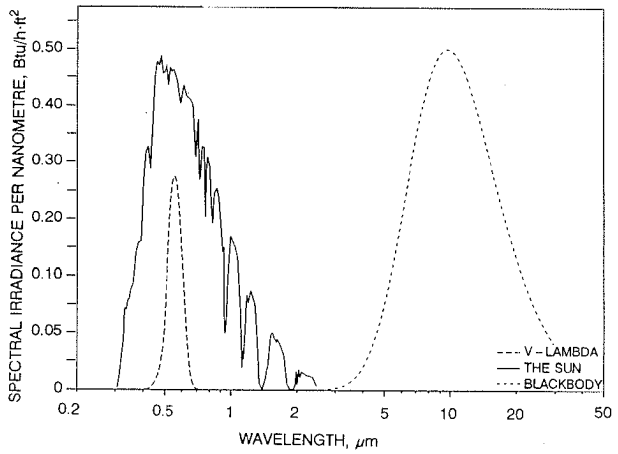

Fig. 10 Terrestrial Solar Spectrum (m = 1.5), V-Lambda Curve, and Blackbody Spectrum of 75°F

Spectral Dependence

Frequency and wavelength are related through the equation

$$\lambda f = c \tag{15}$$

where

λ = wavelength, m
f = frequency, Hz
c = velocity of light = 2.9×10^8 m/s in air at atmospheric pressure

The wavelength dependence of radiometric quantities is denoted with a subscript λ attached to the optical property thus: τ_λ, ρ_λ, α_λ, and ϵ_λ.

Source spectra. Radiation incident on a surface has a distribution of magnitude or spectrum over a range of wavelengths. For terrestrial applications, the solar spectrum after it has been modified by passage through the earth's atmosphere is more important (Figure 5).

In addition to the radiation incident on and reflected by surfaces, all bodies above absolute zero also *emit* radiation. The hotter they are, the more they emit. Also, as the temperature changes, the spectral distribution of the emitted radiation shifts. Figure 10 shows the emission spectrum of a blackbody at 75°F. The spectrum is shifted toward the longer wavelengths, and no visible radiation is produced. Also, the total magnitude of the emission is low.

SOLAR-OPTICAL PROPERTIES OF GLAZING

The solar-optical properties of a glazing are the integrated or total transmittance, reflectance, and absorptance of the glazing to incident solar radiation. If the spectral optical properties (τ_λ, ρ_λ, α_λ) of the glazing and the spectral irradiance E_λ incident on the glazing are known, the solar optical properties can be calculated from the following equation where q stands for τ, ρ, or α.

$$q_e = \frac{\int_0^\infty q_\lambda E_\lambda \, d\lambda}{\int_0^\infty E_\lambda \, d\lambda} \tag{16}$$

Many window glazings do not have strong spectral selectivity over the solar spectrum, so their spectral optical properties can be considered constant. Thus, the transmitted spectral irradiance can be determined by multiplying the incident spectral irradiance $E_{t\lambda}$ by the solar transmittance.

With glazings that have nonuniform spectral transmittances τ_λ, the following integral must be evaluated over the solar spectrum.

$$E_t = \int \tau_\lambda E_\lambda \, d\lambda \tag{17}$$

Table 9 Portions of Total Solar Spectral Irradiance Contained in Portions of Visible Spectrum

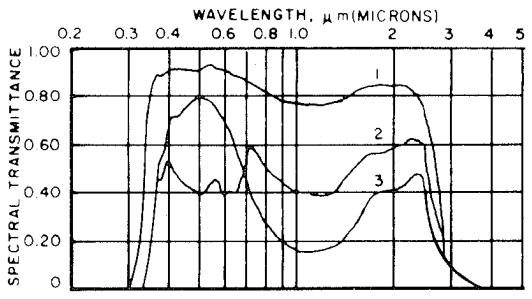
Wavelength, nm		Percent	Percent
Start	End	Irradiance	Illuminance
370	770	54.4	100.0
380	760	52.2	100.0
390	750	50.2	99.9
400	740	47.4	99.9
410	730	44.9	99.8
420	720	41.9	99.8
430	710	39.5	99.8
440	700	36.7	99.8
450	690	35.3	99.5
460	680	31.1	99.1

Note: The integrated total irradiance = 950 W/m² and illuminance = 100 klx (from Figure 10).

Figure 11 shows the normal incidence spectral transmittance of typical glasses. The approximate transmission of total incident solar radiation for clear float glass at an incidence angle of 0° ranges from 86% for 0.09 in. thicknesses to 84% for 0.12 in. thicknesses to 78% for 0.25 in. thicknesses. Actual transmission varies with the amount of iron or other absorbers in the glass. Bronze, gray, and green heat-absorbing glasses, in 0.25-in. thicknesses, transmit between 45 and 49% of the total incident solar radiation (Rubin 1984).

Almost all architectural glass is opaque to the long-wave radiation emitted by surfaces at temperatures below about 250°F. This characteristic produces the greenhouse effect, by which solar radiation passing through a window is partially retained inside by the following mechanism. Radiation absorbed by surfaces within the room is emitted as long-wave radiation, and cannot escape directly through the glass since it is opaque to all radiation beyond 4.5 μm. Instead, the radiation from the room surfaces falling on the glass is absorbed and reemitted to both sides as determined by several parameters, such as the inside and outside film coefficients of heat transfer, the surface emissivities, and other glazing properties.

Figure 12 shows how solar-optical properties vary with incident angle of typical uncoated glazing materials. As the incident angle increases from zero, the transmittance diminishes, reflectance increases, and absorptance first increases because of the lengthened optical path and then decreases as more incident radiation is



1. 1/8-in. regular sheet
2. 1/4-in. gray heat-absorbing plate/float
3. 1/4-in. green heat-absorbing plate/float

Fig. 11 Spectral Transmittance for Typical Architectural Glass

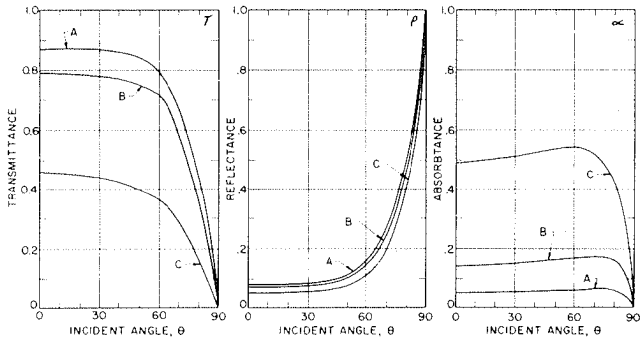


Fig. 12 Variation with Incident Angle of Solar-Optical Properties for Double-Strength Sheet, Clear, and Heat-Absorbing Glass

reflected. For diffuse radiation, the solar-optical properties are close to the direct radiation properties when $\theta = 60°$. Maximum solar gains through vertical glazing usually occur when the solar altitude is 30 to 35° and the surface-solar azimuth is close to zero.

Thermal Infrared Radiation

All the energy of the radiant flux in the solar spectrum becomes heat when it is absorbed, including that in the visible portion of the spectrum, and all this flux is absorbed eventually. If it is all absorbed inside a building, it all becomes heat gain. If some is reflected by a window or shade as it passes through, then the heat gain inside is reduced.

The Stefan-Boltzmann law predicts the integration of the Planck radiation law for blackbodies over all wavelengths as

$$E_b = \sigma T^4 \tag{18}$$

If the ratio of the spectral irradiance E_λ to E_b is constant over the spectral range of output, then Equation (18) can be modified to predict the emitted irradiance of real surfaces as

$$E = \epsilon E_b = \epsilon \sigma T^4 \tag{19}$$

For most windows, only the hemispherical emittance is of interest. As window technology advances, however, angular emittance effects will have to be studied more closely.

Emittance is related to the other optical properties in that a good absorber is a good emitter, and a good reflector is a poor emitter. This is only true at a given wavelength, which is a consequence of Kirchoff's law (Duffie and Beckman 1980):

$$\alpha_\lambda(\theta, \phi) = \epsilon_\lambda(\theta, \phi) \tag{20}$$

where θ and ϕ are angles defining the directional dependence of the spectral absorptance α_λ and spectral emittance ϵ_λ. A surface appearing to be an excellent reflector in the visible portion of the spectrum may have a high emittance over most of the infrared spectrum, or vice versa.

Spectral Selectivity

Suitable, spectrally selective window glazings can be chosen either to trap solar heat or to block its entry into a building. A glazing with spectral selectivity has a surface with one or more of the optical properties that behaves differently in one part of the spectrum than in another.

The terrestrial spectral distribution of irradiance from the sun and the spectral response of the human eye (the V-lambda curve) is shown in Figure 10. The V-lambda function is used to determine the visible portion (illuminance) in broadband radiation. Illuminance is measured in lumens and is the visible equivalent of irradiance. The V-lambda curve is nonzero from 370 to 770 nm, but the values outside the range from 430 to 690 nm are less than 1% of the maximum value at 555 nm (Table 9).

The spectral irradiance from 370 to 770 nm is 54.4% of the total solar irradiance of 300 Btu/h·ft² shown in Figure 10 or 163 Btu/h·ft². This spectral range contains 100% of the light in this spectrum. The spectral irradiance from 450 to 690 nm is 102 Btu/h·ft² or 34% of the total. This spectral range contains about 99.4% of the light in the spectrum. Thus, a perfect spectrally selective filter, which rejects all electromagnetic radiation outside the range from 430 to 690 nm and passes all within this range, would pass 99.4% of the light incident on the filter but only 34% of the heat energy. Spectrally selective filters using multilayer dielectric coatings on glass approach this goal. Their transmittances over the visible portion of the spectrum are not 100%, but some are in excess of 80%.

An ideal filter would pass 99.5% of the light (9300 lumens/ft²) and only 34% of the heat, or 30 W/ft². The luminous efficacy of the emerging radiation would be 9300/30 or 310 lm/W, a factor of 2.9 times the 105.5 lm/W luminous efficacy of the whole spectrum shown in Figure 10.

Windows for heating dominated buildings. The best spectral selectivity for cold climates would have a high transmittance over the entire solar spectrum, admitting the most solar radiant heat, and a low emissivity (high reflectivity) over the long-wavelength infrared radiation spectrum, to reflect low-temperature radiant heat from the walls and room furnishings back into the building. Conventional low-emittance (low-e) windows approximate this ideal performance.

Windows for cooling dominated buildings. Table 9 indicates that the visible portion contains from 30 to 50% of the total energy in the solar spectrum. Thus, by eliminating all the solar ultraviolet and infrared radiation transmitted by window glazing, outside the visible spectrum (and even some of the radiation at each end of the visible portion), from 50 to 70% of the solar radiant heat gain could be eliminated with no significant loss of light transmission through the glazing (Figure 13).

Window systems are available with glazing coatings that approximate this ideal spectral selectivity. Most also have low emittance in the long-wavelength, infrared portion of the spectrum. These coatings also block some of the visible spectrum. The effects of this selectivity on the color of the transmitted light and its color-rendering properties must also be considered in the design.

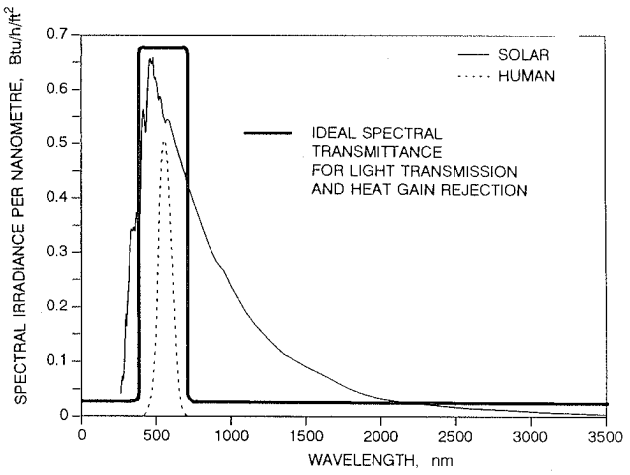

Fig. 13 Comparison of Extraterrestrial Spectrum and Human Visibility Function with Ideal Filter Transmittance Spectrum

Absorbed Solar Radiation

The absorbed radiation, including ultraviolet, visible, and infrared, is turned to heat inside the absorbing material. In a window, the glazing loses the heat through conduction, convection, and radiation. Some heat goes outside the building, and the remainder adds to the directly transmitted solar heat gain. The size of this inwardly flowing fraction depends on the nature of the air boundary layers adjacent to both sides of the glazing, including any gas trapped between the panes of a multiple-glazed window.

If E_t is the incident solar irradiance (outside), τ_s is the solar transmittance, α_s is the solar absorptance, and N_i is the inwardly flowing fraction of the absorbed irradiance for a single pane of glass, the solar gain q_i (inside) is

$$q_i = E_t(\tau_s + N_i \alpha_s) \tag{21}$$

The quantity in parentheses is the solar heat gain coefficient (SHGC). It is the fraction of incident irradiance that enters through the glazing as heat gain. It includes both the directly transmitted portion τ_s and the absorbed and reemitted portion $N_i\alpha_s$. The SHGC is needed to determine the solar radiant heat gain from a window. The SHGC should be included, along with window U-factor and other properties, in any description of a window's energy performance.

The total rate of heat flow inward (Vild 1964) by radiation and convection from an unshaded single glazing is

$$q_{RCi} = E_t(\tau_S + N_i \alpha_S) + U(t_o - t_i) \tag{22}$$

where

N_i = inward-flowing fraction of absorbed radiation
E_t = incident irradiance

For unshaded single glazing, $N_i = U/h_o$, and Equation (22) becomes:

$$q_{RCi} = U\left[\frac{\alpha E_t}{h_o} + t_o - t_i\right] + E_o\tau_s \tag{23}$$

Shading Coefficient

Tables in this chapter list data that may be used to calculate heat gain through a standard reference glazing system. The shading coefficient is a widely used indicator of solar gain that was devised as a convenient way to convert these numbers to equivalent values for different glazing systems. It is defined as the ratio of the solar gain q_i of the window to that of a standard reference window of single-pane, double-strength clear glass, irradiated in the same way and under the same environmental conditions. It is, therefore, equal to the ratio of solar heat gain coefficients of the two windows

$$SC = \frac{SHGC_{Test}}{SHGC_{Ref}} = \frac{\tau_{Test} + N_{i,\,Test}\,\alpha_{Test}}{\tau_{Ref} + N_{i,\,Ref}\,\alpha_{Ref}} \tag{24}$$

If the reference window's SHGC is constant, then the SC would differ from the SHGC only by a constant multiplier. However, in general, the SHGC is a function of the direction of incidence of the radiation as well as its spectral distribution. This is true both of the reference window and the test window.

As fenestration systems become more complex, however, the shading coefficient is being replaced by the solar heat gain coefficient (McCluney 1991). For energy analyses, including hourly building performance simulation calculations, the angle-dependent values of the solar heat gain coefficient give better results than the shading coefficient (McCluney 1987).

Data on solar heat gain coefficients are available from some manufacturers of fenestration products. Computer programs are available for calculating solar heat gain factors (incident solar irradiances and solar heat gains per unit area of glazing area) automatically (LBL 1992).

Solar Gain for Complex Multipane Windows

For multiple-pane windows with gas fills other than air and with spectrally selective coatings on one or more of the glazing surfaces, the foregoing equations are inadequate for determining the solar heat gain coefficient, and they do not explicitly include angle-dependent and spectrally selective effects. LBL (1992) has developed a calculation procedure and computer program (WINDOW 4.0) that performs the needed calculations for determining this coefficient for complex windows where the glazings do not exhibit significant scattering effects and where the glazing coatings have known angle-dependent optical properties.

The National Fenestration Rating Council (NFRC) is working to standardize this procedure for use in a national fenestration certification and labeling program. Until such a standard is available, the fenestration manufacturer should be consulted for data on the angle-dependent SHGC of its products.

Frame and Other Nonglazing Elements

Solar radiant heat also enters a building through opaque elements such as the frame and any mullion bars and dividers that are part of the fenestration system. A solar heat gain coefficient can be defined for these opaque elements and used to determine the overall solar gain q_i of the fenestration system as follows

$$q_i = E_t\left(A_g F_g + A_f F_f + \sum_{i=1}^{N} A_i F_i\right) \tag{25}$$

where

A_g = area of glazing with solar heat gain coefficient F_g
A_f = area of frame with solar heat gain coefficient F_f
A_i = area of the i^{th} additional opaque element having F_i as its solar heat gain coefficient

The overall, area-weighted solar heat gain coefficient $< F >$ can be defined by

$$< F > = \frac{\sum_{i=1}^{M} A_i F_i + A_g F_g + A_f F_f}{\sum_{i=1}^{M} A_i + A_g + A_f} \tag{26}$$

where M is the total number of different opaque and transparent elements over the total area of the fenestration aperture.

Passive Solar Gain

Energy analysis of a fenestration product should include the value of passive solar gain through the product in winter. As described in Chapter 30 of the 1991 ASHRAE *Handbook—Applications*, the magnitude of this energy gain depends on such variables as latitude and orientation. In some cases, properly designed and operated fenestration allows more energy into the building over a heating season than it loses, thus making it energy contributing rather than energy consuming. Excessive solar gain must be controlled during the cooling season, however.

Solar Gain Rejection

For some buildings in certain climates, preventing solar gain is more important from an energy perspective than improved thermal insulation using multiple panes of glazing. For example, internal load-dominated buildings in cool, clear climates can have

substantial daytime solar and internal heat gains. These gains can be rejected by conduction through the building envelope and/or forced ventilation through the HVAC system. Preventing excessive solar gain through the fenestration systems of such buildings is very important. If such a building is occupied and conditioned mostly during daylight hours, improving the U-factor of the windows can have an overall adverse impact on building energy performance, preventing the escape of heat by conduction through the windows, and requiring the HVAC system to remove this heat even when the outside air temperature is substantially below the inside temperature.

AIR MOVEMENT

Infiltration through Fenestration

Air infiltration through fenestration products is significant in determining a building's heating and cooling loads. It should be analyzed separately and not incorporated in a U-factor determination for any specific product. Chapter 23 presents calculation procedures for air infiltration.

Indoor Air Movement

Because supply air grilles are frequently located directly below windows, air sweeps the interior glass surface. Heated supply air should be directed away from the glass to prevent large temperature differences between the center and edges of the glass. These thermal effects must be considered, particularly when annealed glass is used and air is forced over the glass surface during the heating season. Direct flow of heated air over the glass surface can increase the heat transfer coefficient and the temperature difference, causing a substantial increase in heat loss; it may also lead to thermally induced stress and risk of glass breakage.

Systems designed predominantly for cooling lower the glass temperature and rapidly pick up the cooling load. Both tend to improve the comfort condition of the space. However, the air-conditioned space has an increased net heat gain, caused by (1) increase in the shading coefficient (SC) due to delivery of a larger portion of the absorbed heat to the indoor space; (2) increase in the fenestration U-factor, because of the greater convection effect at the indoor surface; and (3) increase in the air-to-air temperature difference, since supply air rather than room air is in contact with the indoor glass surface. The principal increase in heat gain with clear glass is the result of the higher U-factor and the greater air-to-air temperature difference, since supply air, rather than room air, is in contact with the indoor glass surface.

The principal increase in heat gain with clear glass is the result of the higher U-factor and the greater air-to-air temperature difference. McCabe *et al.* (1986) showed that the SC for heat-absorbing glass is much larger than that for clear glass (Figures 14 and 15).

When supply air flows between glass and an interior shading device, a greater portion of the heat absorbed in a shading device is added to the total heat gain. Pennington and McDuffie (1970) used this arrangement with a medium-colored drape to show an approximate 20% increase over the natural convection condition (Figures 16 and 17).

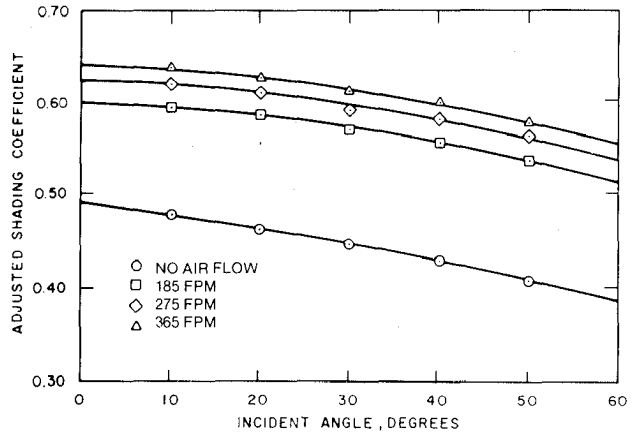

Fig. 17 Theoretically Determined Shading Coefficients for 0.25-in. Green Heat-Absorbing Plate Glass with Drape

Table 10 U-Factors for Summer Conditions, Btu/h·ft²·°F

Type	Velocity of Air Sweeping Window			Still Air
	365 fpm	275 fpm	185 fpm	
CL and CL	0.673	0.658	0.64	0.56
HA and CL	0.673	0.658	0.64	0.56
Refl. and CL	0.378	0.378	0.367	0.34

CL = Clear 0.25-in. float; HA = Heat absorbing 0.25-in. float; Refl = 0.25-in. reflective float.

Insulating glass exhibits the same effects as single glass for the same reasons, but they are less marked. Figure 18 shows theoretically determined SC curves for three types of insulating glass at three different airflow rates and for still air. Figure 19 shows similar curves for glass and drape arrangements, with the supply air delivered between the glass and drape. Pennington *et al.* (1973) experimentally checked the theoretical curves for both single and insulating glass arrangements with good agreement. Table 10 shows theoretically determined U-factors for the three insulating glass types. The values shown for still air conditions were verified experimentally by Pennington *et al.* (1973).

The theoretical determination of the SC, U-factor, and total heat gain when the supply air sweeps the indoor glass surface is similar to that explained in the section Fenestration Heat Balance—Solar Heat Gain. Instead of a combined air space conductance value h_s, convection and radiation effects must be calculated separately for spaces where the surfaces are swept by the supply air. An iterative computer solution is necessary to determine temperatures of the fenestration components.

Equation (27) may be used to calculate heat gain through the center of a single-glass fenestration; convection and radiation components for the interior glass surface are calculated separately.

$$q_A = E_{\tau g} + h_c (t_g - t_{aa}) + \sigma e_g (T_g^4 - T_r^4) \qquad (27)$$

where

q_A = total heat gain, Btu/(h·ft²)
$E_{\tau g}$ = transmitted solar energy, Btu/(h·ft²)
h_c = inside glass surface convection coefficient = 0.99 + 0.21V, Btu/(h·ft²·°F)
V = air velocity, fps
t_g = temperature of glass, °F
T_g = temperature of glass, °R
t_{aa} = average temperature of air sweeping glass, °F
T_r = room air temperature, °R
σ = Stefan-Boltzmann constant
e_g = hemispherical emittance of room side glass surface

Since the equation has two unknowns, q_A and t_g, a second equation is needed

$$E_{\alpha g} = h_o (t_g - t_{oo}) + h_c (t_g - t_{aa}) + \sigma e_g (T_g^4 - T_r^4)$$

where

$E_{\alpha g}$ = solar energy absorbed in glass, Btu/(h·ft²)
h_o = surface coefficient = 4.0 Btu/(h·ft²·°F)
t_o = outdoor air temperature, °F

The U-factor may be determined by

$$U = 1/(1/h_o + 1/h_i + L/k) \qquad (28)$$

where

h_i = inside glass surface combined radiation and convection coefficient, Btu/(h·ft²·°F)
L/k = glass thickness, in., over thermal conductivity, Btu·in/(h·ft²·°F)

The air-to-air heat gain is expressed by

$$q_{td} = U (t_o - t_{aa}) \qquad (29)$$

The solar heat gain is $q_A - q_{td}$.

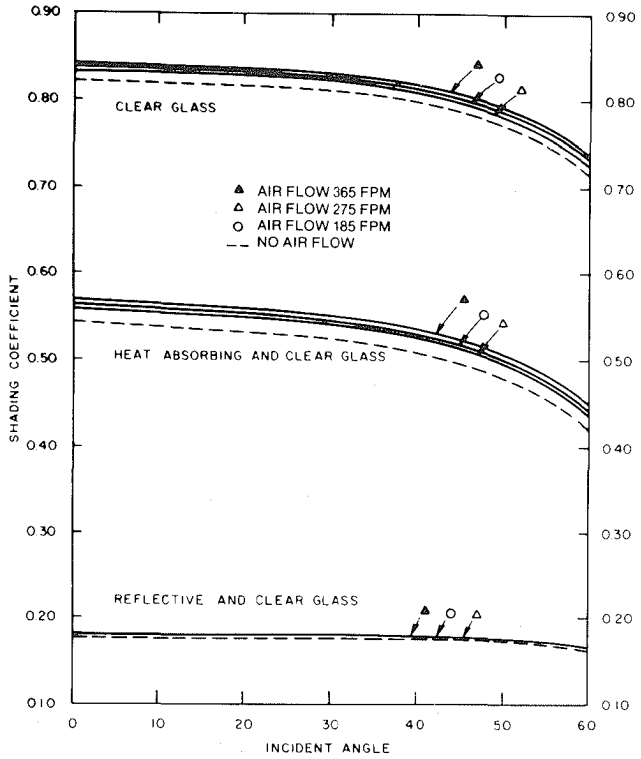

Fig. 18 Theoretically Determined Shading Coefficients for Three Insulating Glass Types

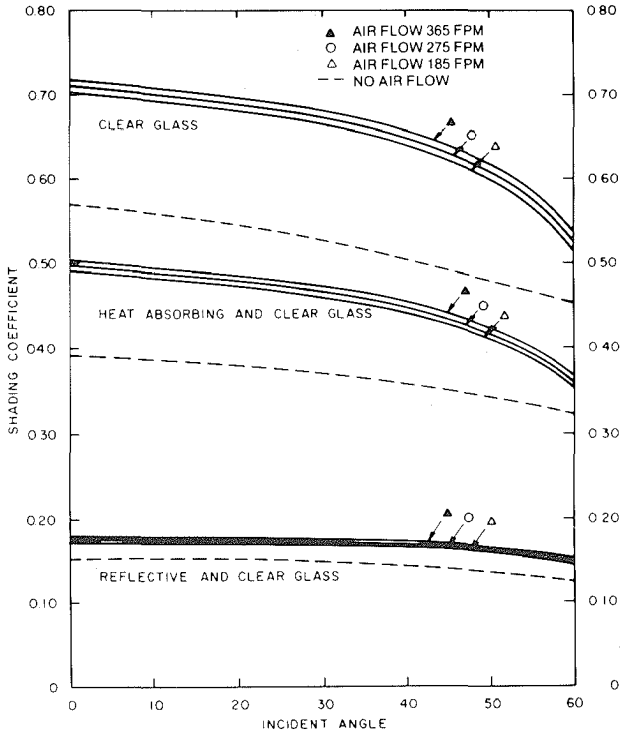

Fig. 19 Theoretically Determined Shading Coefficients for Three Insulating Glass Types with Medium Colored Drapes

DAYLIGHTING FROM FENESTRATION

In the United States, a general rule has been that the fenestration area should be at least 20% of the floor area. In Europe, a similar rule was based on a minimum illumination value on the normal work plane from a standard overcast sky condition.

The secondary visual benefit of fenestration is the amount and quality of light it produces in the work environment. One general rule determined the need for auxiliary electric light by assuming that daylight was adequate for a depth of two and one-half times the height of the window into the room based on a normal sill height. To prevent excessive glare, all fenestration should have sun controls. Variable and removable controls are often more effective in daylight than fixed controls.

For more accurate evaluation of daylight distribution within a space, several prediction tools, such as the *Recommended Practice of Daylighting* (IES 1979), are available. This practice shows a simple way of calculating the daylight distribution on the work plane from windows and skylights with and without controls. Many other daylight prediction tools calculate illuminance from radiant flux transfer or ray tracing.

Any or all of the various daylight prediction tools can be used to compare the relative value of daylight distribution from alternative fenestration systems, but ultimately the designer must evaluate costs and benefits to choose between alternative designs. This may be based on energy use or, more properly, on overall costs and benefits to the client. A simplified prediction tool, BEEM, is available for such analysis (Rundquist 1991). Also, total loss of productivity from an electric brown-out in a space with no natural ventilation or daylight may be as important as the benefits of many energy saving schemes.

SIMPLIFIED METHODS FOR PREDICTING HEAT TRANSFER THROUGH FENESTRATION

Fenestration Heat Balance-Solar Heat Gain

At any instant, the heat balance between a unit area of sunlit single-glazing material and its thermal environment, as shown in Figure 20, is

$$E_t + U(t_o - t_i) = q_R + q_s + q_T + q_{RCo} + q_{RCi} \qquad (30)$$

where q_R, q_s, and q_T represent the heat reflected, stored in the glass, and transmitted, respectively. In general, q_s is relatively small in magnitude, so it is disregarded. The terms q_{RCo} and q_{RCi} are the rates of heat flux outward and inward, respectively, by radiation and convection. The rate of heat rejection to the atmosphere is the sum of the reflected heat q_R and outward radiation convection heat flux q_{RCo}.

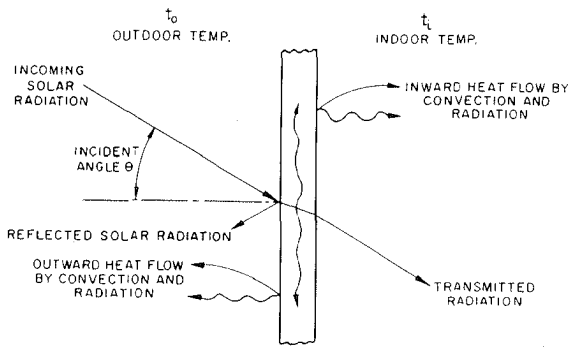

Fig. 20 Instantaneous Heat Balance for Sunlit Glazing Material

The total instantaneous rate of heat gain through the glazing material may be expressed:

Total heat admission through glass = Radiation transmitted through glass + Heat flow inward by radiation-convection from inner glass surface

$$q_A = E_{D\tau D} + E_{d\tau d} + q_{RCi} \qquad (31)$$

Subscript D denotes direct radiation; d denotes diffuse radiation, and τ indicates the transmitted portion. The solar-optical properties for diffuse radiation can be taken as those for direct radiation where $\theta = 60°$. The following equations consider total solar energy values for simplicity.

This equation may also be written as:

Total heat admission through glass = Radiation transmitted through glass + Inward flow of absorbed solar radiation + Heat flow due to outdoor-indoor temperature difference

For single glazing,

$$q_A = E_t\tau + N_i(\alpha E_t) + U(t_o - t_i) \qquad (32)$$

For double glazing, the transmittance through both glasses can be calculated by

$$\bar{\tau} = \tau_o\tau_i/(1 - \rho_2\rho_3) \qquad (33)$$

Since the first two terms of Equation (32) are related to the incident solar radiation, while the third occurs whether or not the sun is shining, Equations (32) and (33) may be combined as

$$q_A = E_t\bar{\tau} + N_{jo}(\alpha E_o) + N_i(\alpha E_i) + U(t_o - t_i) \qquad (34)$$

Total heat admission through glass = Solar heat gain + Conduction heat gain

These may both be written as

$$q_A = FE_t + U(t_o - t_i) \qquad (35)$$

where

q_A = instantaneous rate of heat admission through fenestration, Btu/h·ft²
F = dimensionless ratio of solar heat gains to incident solar radiation

The solar heat gain coefficient F is a characteristic of each type of fenestration and varies with the incident angle, since transmittance and absorptance of the glazing material depend on θ. For single glazing

$$F = \tau + U\alpha/h_o \qquad (36)$$

For double glazing

$$F = \tau + U\alpha_o/h_o + [(U/h_o) + (U/h_s)]\alpha_i \qquad (37)$$

For shaded glazing materials and other more complex fenestration, F can be calculated for standard conditions, but such values should be verified by solar calorimeter tests.

Because of the constantly growing number of fenestration products and the great variety of combinations of incident angle and solar radiation intensity, the quantities in Equation (37) cannot be estimated in all conditions. Instead, a procedure described in the following section has been developed for estimating solar and total heat gains through fenestration (Vild 1964, Yellott 1966, Pennington *et al.* 1964, Smith and Pennington 1964).

Solar Heat Gain Factors and Shading Coefficients

The reference glazing material for the following calculations is double-strength sheet glass (DSA) with 0.86 transmittance, 0.08 reflectance, and 0.06 absorptance at normal incidence. For other incident angles, Figure 11 gives the solar-optical properties.

The shading coefficient (SC) is the ratio of solar heat gain through a glazing system under a specific set of conditions to solar gain through a single pane of the reference glass under the same conditions. This ratio, a unique characteristic of each type of fenestration, is represented by

$$SC = \frac{\text{Solar heat gain of fenestration}}{\text{Solar heat gain of reference glass}} \quad (38)$$

The SC is a ratio of the solar heat gain coefficient F for the fenestration and F for single-pane, double-strength, clear (DSA) glass, which, for standard summer conditions, is 0.87 for normal incidence.

$$SC = \frac{F \text{ of Fenestration}}{0.87} = 1.15\,(F \text{ of Fenestration}) \quad (39)$$

Table 11 gives values of SC for frequently used fenestrations.

For this calculation procedure, heat gains through sunlit DSA glass are designated as the solar heat gain factors (SHGF). Tables 12 through 18 give solar intensity and SHGF values calculated for daylight hours of the 21st day of each month. The tables apply solar-optical properties of DSA glass and the incident angles, which apply to 16 orientations for latitudes in 8° increments from 16 to 64° North. For other dates, times, and latitudes, use linear interpolation.

Table 11 Shading Coefficients for Single Glass and Insulating Glass

Type of Glass	Nominal Thickness[a]	Solar Trans.[a]	Shading Coefficient $h_0 = 4.0$	Shading Coefficient $h_0 = 3.0$
A. Single Glass				
Clear	1/8 in.	0.86	1.00	1.00
	1/4 in.	0.78	0.94	0.95
	3/8 in.	0.72	0.90	0.92
	1/2 in.	0.67	0.87	0.88
Heat absorbing	1/8 in.	0.64	0.83	0.85
	1/4 in.	0.46	0.69	0.73
	3/8 in.	0.33	0.60	0.64
	1/2 in.	0.24	0.53	0.58
B. Insulating Glass				
Clear out, Clear in	1/8 in.[b]	0.71[c]	0.88	0.88
Clear out, Clear in	1/4 in.	0.61	0.81	0.82
Heat absorbing out, Clear in[d]	1/4 in.	0.36	0.55	0.58

Table refers to factory-fabricated units with 3/16, 1/4, or 1/2-in. air space or to prime windows plus storm sash.
[a]Refer to manufacturer's literature for values.
[b]Thickness of each pane of glass, not thickness of assembled unit.
[c]Combined transmittance for assembled unit.
[d]Refers to gray, bronze, and green tinted heat-absorbing float glass.

The SHGF in Tables 12 through 18 do not represent maximum values but the conditions on average cloudless days. For high elevations and very clear atmospheres, the maximum SHGF can be as much as 15% above the tabulated values. For very dusty industrial atmospheres and exceptionally humid locations, they may be from 20 to 30% lower than the tabulated values. The Clearness numbers in Figure 7 can be used for these conditions.

Half-day totals given in Tables 12 through 18 are integrated values using Simpson's rule for integration, with a 10-min. time interval starting at 0100 solar time. Similar integration by hourly periods results in less accurate values, because of the variation of SHGF within this longer time interval. Full-day totals can be estimated from these tables by adding the morning half-day total for the orientation, listed at the top, to the afternoon half-day total for the same orientation, listed at the bottom of the tables.

For any glazing material or fenestration other than double-strength sheet glass, but with a similar angular dependence, the solar heat gain will be:

$$\begin{matrix}\text{Solar}\\ \text{heat}\\ \text{gain}\end{matrix} = \begin{matrix}\text{Shading}\\ \text{coefficient}\\ \text{for fenestration}\end{matrix} + \begin{matrix}\text{Solar heat gain factor}\\ \text{for given orientation}\\ \text{and existing conditions}\end{matrix} \quad (40)$$

The total instantaneous heat gain is

$$q_A = (SC)(SHGF) + U(t_o - t_i) \quad (41)$$

Equation (41) applies at any time of the year. In winter, when outdoor temperature is lower than indoor, the conduction heat flow occurring in the absence of sunshine is negative or outward in summer, conduction heat flow is usually inward.

To estimate the total gain through fenestration at any time, applicable values of outdoor and indoor dry-bulb temperatures must be used. Tables in Chapter 24 give design values of summer outdoor dry-bulb temperatures for many locations. These are generally mid-afternoon temperatures; for other times, local weather stations can supply appropriate temperature data. Winter design temperatures should not be used in Equation (40), since they are usually given for early morning hours before sunrise. The indoor air temperature for air-conditioned spaces is likely to be closer to 75°F than to 80°F (see Chapter 24).

Example 8. Find the total heat gain through the center of a double-glazed window consisting of an outdoor light of 0.25-in. clear glass, 0.5-in. air space, and an indoor light of 0.25-in. clear glass, with a reflective film on the No. 3 surface in a west wall at 40° North latitude, at 1600 on July 21. Outdoor air is 105°F, and indoor air is 75°F. Solar irradiance is 248.3 Btu/(h·ft²).

The spectrally averaged data for the glass are:

Outdoor $\tau = 0.80$; $\rho_1 = 0.07$; $\rho_2 = 0.07$; $\alpha_1 = 0.13$; $\alpha_2 = 0.13$; $e_1 = 0.84$; $e_2 = 0.84$

Indoor $\tau_i = 0.12$; $\rho_3 = 0.70$; $\rho_4 = 0.45$; $\alpha_3 = 0.18$; $\alpha_4 = 0.81$; $e_3 = 0.10$; $e_4 = 0.84$

Solution:
Absorption for the glasses

$$\alpha_o = 0.13 + (0.13)\frac{0.80 \times 0.70}{1 - (0.07 \times 0.70)}$$

$$\alpha_i = (0.18)\frac{0.80 \times 0.70}{1 - (0.70 \times 0.70)} = 0.151$$

The solar radiation absorbed

$$\alpha E_o = 248.3 \times 0.207 = 51.4 \text{ Btu/h·ft}^2$$
$$\alpha E_i = 248.3 \times 0.151 = 37.5 \text{ Btu/h·ft}^2$$

Solar Heat Gain Factors, Btu/(h·ft²)																		

Notes: 1. Clearness number = 1.00; Ground reflectance = 0.20. 2. Figures shown are for 21st day of each month.

Next, the center of glazing U-factor for the fenestration must be found. The effective emittance of the air space is

$$e = \frac{1}{(1/e_2) + (1/e_3) - 1} = \frac{1}{(1/0.84) + (1/0.1) - 1} = 0.098$$

Air space and indoor coefficients are determined by trial and error.

Assume the outdoor and indoor glass temperatures are 115 °F and 105 °F, respectively. The mean temperature is 110 °F and the temperature difference 10 °F. From Table 4, $h_s = 0.51$. The indoor coefficient from Table 3 is $h_i = 1.59$ for $e_g = 0.84$. The thermal resistance of 0.25-in. thick glass is 0.035 °F · ft²/Btu. Thus, for an outdoor coefficient of $h_o = 4.0$ Btu/(h · ft² · °F)

$$U = \frac{1}{(1/4.0) + (0.035) + (1/0.51) + 0.035 + (1/1.59)}$$

The inward radiation and convection gain is

$$q_{RCi} = 0.344\left[\frac{51.4}{4.0} + 37.5\left(\frac{1}{4.0} + \frac{1}{0.51}\right) + (105 - 75)\right]$$

$$= 43.3 \text{ Btu/(h} \cdot \text{ft}^2\text{)}$$

Find the glass temperatures to check on first assumed values of $t_{go} = 115$ °F and $t_{gi} = 105$ °F (inside and outside temperatures, respectively).

$$t_{go} = t_o + (\alpha E_o + E_i - q_{RCi})(1/h_o + R_{go}/2)$$
$$= 105 + (51.4 + 37.5 - 43.3)(1/4.0 + 0.035/2) = 117.2\,°\text{F}$$

and $t_{gi} = t_i + g_{RCi}(1/h_i + R_{gi}/2)$

$$t_{gi} = 75 + 43.3\,(1/1.59 + 0.035/2) = 103.0\,°\text{F}$$

The glass temperatures approximate the assumed temperatures, but repeating the previous calculations for a mean temperature of 110.1 °F and a new temperature difference of 14.2 °F for the space by interpolation results in an $h_s = 0.515$, and an $h_i = 1.57$ and

$$U = 0.345 \text{ Btu/h} \cdot \text{ft}^2 \cdot \text{°F}$$

where

$q_{RCi} = 43.1$ Btu/h · ft²
$t_{go} = 116.3$ °F
$t_{gi} = 103.0$ °F

Transmittance through both panes of glass is

$$\tau = (0.80 \times 0.12)/[1 - (0.07 \times 0.70)] = 0.101$$

The F factor for the fenestration is

$$F = 0.101 + \frac{0.345}{4.0}(0.207) + \left(\frac{0.345}{4.0} + \frac{0.345}{0.515}\right)(0.151) = 0.233$$

The shading coefficient is

$$\text{SC} = 0.233/0.87 = 0.268$$

The total heat gain is

$$q_A = 0.268\,(216) + 0.345(105 - 75) = 68.2 \text{ Btu/(h} \cdot \text{ft}^2\text{)}$$

Solar Heat Gain Factors for Ground Reflectances Other Than 0.20

The SHGF tables have been computed using a ground reflectance of 0.20. For other foreground reflectance values, computer calculations can be made. For hand computations, the SHGF can be adjusted for the different SHGF of the new foreground reflectances (see Table 19).

Table 19 Solar Reflectances of Foreground Surfaces

	Incident Angle					
Foreground Surface	**20°**	**30°**	**40°**	**50°**	**60°**	**70°**
New concrete	0.31	0.31	0.32	0.32	0.33	0.34
Old concrete	0.22	0.22	0.22	0.23	0.23	0.25
Bright green grass	0.21	0.22	0.23	0.25	0.28	0.31
Crushed rock	0.20	0.20	0.20	0.20	0.20	0.20
Bitumen and gravel roof	0.14	0.14	0.14	0.14	0.14	0.14
Bituminous parking lot	0.09	0.09	0.10	0.10	0.11	0.12

Adapted from Threlkeld (1962).

Equation (22) can be used to estimate the ground-reflected diffuse radiation falling on a vertical surface. However, the SHGF for a horizontal fenestration is approximately 87% of the total solar radiation falling on a horizontal surface. By using this SHGF in Equation (22) instead of the solar radiation incident on the ground, the ground-reflected contribution to the vertical SHGF will be in the same units. The incident ground-reflected diffuse radiation for the reference reflectance of 0.20 in terms of the SHGF is given by Equation (22)

$$0.87\,E_{dg} = \text{SHGF} \times 0.20 \times 0.5$$

where 0.87 is the conversion from incident solar radiation to SHGF, SHGF is the value for the horizontal surface, 0.20 is the reference ground reflectance, and 0.5 is the F_{sg} angle factor for vertical surfaces.

The ground component for the new reflectance may be calculated in the same manner, or by means of a ratio of the reflectances and the difference applied to the SHGF for the vertical surface.

Example 9. Find the adjusted SHGF for a foreground having a reflectance of 0.32, for an east-facing window at 1000, July 21, 40° North latitude.

Solution: The SHGF for the horizontal surface, from Table 15, is 231 Btu/(h · ft²). The ground-reflected contribution to the SHGF for the east window, by Equation (22), is

$$0.87\,E_{dg} = 231 \times 0.20 \times 0.5 = 23.1 \text{ Btu/h} \cdot \text{ft}^2$$

For a foreground reflectance of 0.32, it becomes

$$0.87\,E_{dg} = 231 \times 0.32 \times 0.5 = 37.0 \text{ Btu/h} \cdot \text{ft}^2$$

The increase in the SHGF for the higher ground reflectance is 37.0 − 23.1 = 13.9 Btu/h · ft². The SHGF, from Table 15 for the east window, is 146 Btu/h · ft²; and, for the 0.32 ground reflectance, the adjusted SHGF becomes 146 + 13.9 = 159.9 Btu/h · ft².

Computer Calculation of Solar Heat Gain Factors

The following equations can be used to generate SHGF, where all angles are in degrees. The solar azimuth θ and the surface azimuth ψ are measured in degrees from south; angles to the east of south are negative, and angles to the west of south are positive.

Variables

H = hour angle
L = latitude
δ = declination
β = solar altitude
ϕ = solar azimuth
ψ = surface azimuth
γ = surface-solar azimuth
Σ = surface tilt
θ = incident angle
A = apparent solar constant
B = atmospheric extinction coefficient
C = sky diffuse factor
E_{DN} = direct normal irradiance

E_D = direct irradiance
Y = ratio of vertical/horizontal sky diffuse
E_{ds} = diffuse sky irradiance
ρ_g = ground reflectance
E_{dg} = diffuse ground reflected irradiance
E_d = diffuse irradiance
t_j = transmission coefficients for glass
a_j = absorption coefficients for glass
N_i = heat transfer factor, inward flow fraction
τ_D = transmittance of DSA glass
α_D = absorptance of DSA glass

Values of A, B, and C are given in Table 7 for the 21st day of each month. Values for other dates can be obtained by interpolation. The transmission and absorption coefficients for DSA glass are given in Table 20. The absorption or transmission of direct solar radiation incident at an angle θ is

$$\alpha_D = \sum_{J=0}^{5} \alpha_j \cos^j \theta \quad (42)$$

$$\tau_D = \sum_{j=0}^{5} t_j \cos^j \theta \quad (43)$$

Note that this calculation procedure, using the coefficients found in Table 20, gives a normal transmittance for DSA glass of 0.88, which is slightly higher than values used elsewhere in this chapter.

Tables 12 through 18 are based on a ground reflectance ρ_g of 0.2 and a heat transfer factor, inward flow fraction N_i of 0.267.

Hour angle, degrees $H = 0.25$ (minutes of time from local solar noon)

Solar altitude β $\sin\beta = \cos L \cos\delta \cos H + \sin L \sin\delta$

Solar Azimuth ϕ $\cos\phi = \dfrac{\sin\beta \sin L - \sin\beta}{\cos\beta \cos L}$

Surface-solar azimuth $\gamma = \phi - \psi$

Incident angle θ $\cos\theta = \cos\beta \cos\gamma \sin\Sigma + \sin\beta \cos\Sigma$

Direct normal irradiance E_{DN} $E_{DN} = A \exp(-B/\sin\beta)$

Direct irradiance E_D $E_D = E_{DN} \cos\theta$ if $\cos\theta > 0$
$E_D = 0$ otherwise

Ratio of sky diffuse on vertical surface to sky diffuse on horizontal surface Y If $\cos\theta > -0.2$
$Y = 0.55 + 0.437\cos\theta + 0.313\cos^2\theta$
otherwise, $Y = 0.45$

Diffuse irradiance E_d $E_d = E_{ds} + E_{dg}$

where

Vertical surfaces $E_{ds} = CY E_{DN}$

Surfaces other than vertical $E_{ds} = CE_{DN}(1 + \cos\Sigma/2)$

and $E_{dg} = E_{DN}(C + \sin\beta)\rho_g(1 - \cos\Sigma)/2$

Solar heat gain

Transmitted component $= E_D \sum_{j=0}^{j=5} t_j \cos^j\theta + E_d^2 \sum_{j=0}^{5} t_j/(j+2)$

Absorbed components $= E_D \sum_{j=0}^{5} a_j \cos^j\theta + E_d^2 \sum_{j=0}^{5} a_j/(j+2)$

Solar heat gain factor = Energy transmitted + N_i (Energy absorbed)

Table 20 Coefficients for DSA Glass for Calculation of Transmittance and Absorptance

i	a_j	t_j
0	0.01154	−0.00885
1	0.77674	2.71235
2	−3.94657	−0.62062
3	8.57881	−7.07329
4	−8.38135	9.75995
5	3.01188	−3.89922

Values of SC given in Table 11 are based on an incident solar radiation equivalent to a SHGF of 216 Btu/(h·ft²). This value corresponds approximately with the SHGF for July 21 through September 21 for a west-oriented window at 1600 sun time for north latitudes from 16 to 40°. The angles of incidence for these times and latitudes are 36, 32, and 30° for July 21, August 21, and September 21, respectively. These low-incidence angles permit use of normal incidence solar properties of the fenestration without adjustment for angular effects. Figure 11 shows how the solar optical properties of glass varies with angle of incidence.

The values of SC given in Table 11 are based on still air (natural convection) at the inner surface of the fenestration and 7.5 mph wind at the outer surface. For these conditions, h_i is about 1.46 Btu/(h·ft²·°F) (Table 3 gives specific values), and h_o is 4.0 Btu/(h·ft²·°F), so the inward flowing fraction of absorbed heat for single glazing is

$$N_i = h_i/(h_i + h_o) = 1.46/5.46 = 0.267$$

Note: Resistance of the glass plate is neglected.

For other indoor and outdoor conditions, the surface coefficients vary over a considerable range, and N_i will also change. Figure 21 shows the variation in SC caused by these changes in surface coefficients. For comparison, Table 11 also lists SC for $h_o = 3.0$. The designer should be aware of the possible variations upward and downward in the SC for any fenestration when the surface conditions vary from still air and 7.5 mph wind at the inner and outer surfaces, respectively.

The SC for any fenestration will rise above the tabulated values when the inner surface coefficient is increased because of forced airflow over that surface and when the outer surface coefficient is decreased by lower wind velocity. Conversely, the SC will fall somewhat below the tabulated values when the air at the inner surface is still and the wind velocity rises above 7.5 mph.

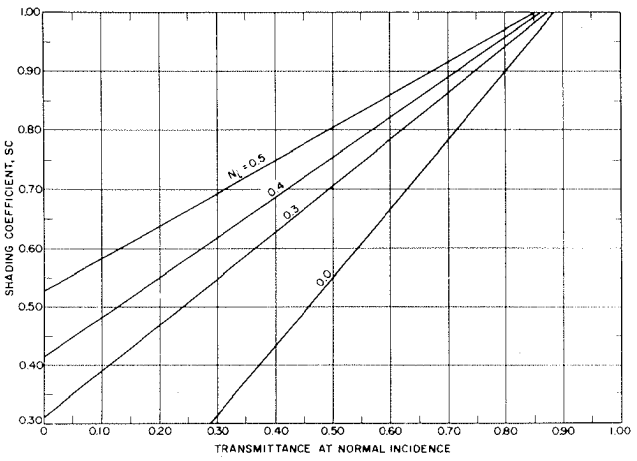

Fig. 21 Shading Coefficient versus Transmittance

The SC and SHGC given in Table 11 and Figure 21 are for uncoated single glass, in which the reflectivity ranges downward from 0.08 for double-strength sheet to 0.05 for 0.25-in. heat-absorbing plate or float. If solar-reflective films or coatings are used, the absorptance is reduced for any given transmittance value. Hence, less absorbed heat flows inward, and the SC is reduced below the tabulated values. For coated single glass with higher reflectivities, SC is given as a function of transmittance and reflectance in Figure 22.

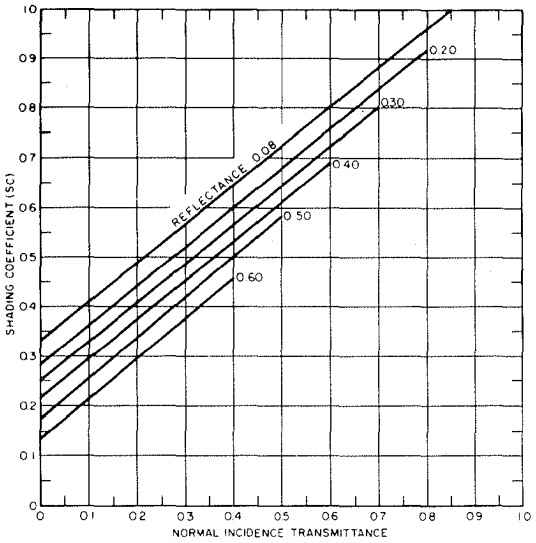

Fig. 22 Approximate Shading Coefficient versus Transmittance and Reflectance for Coated Single Glass

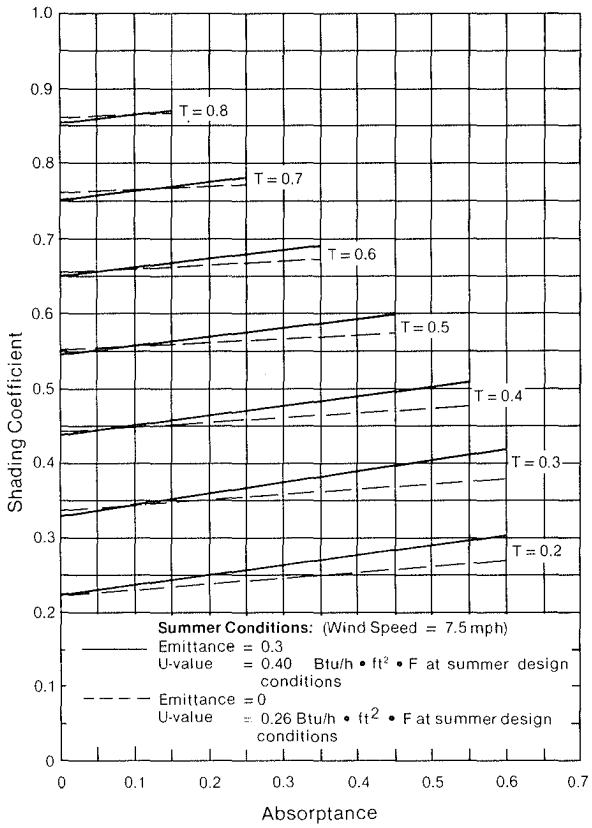


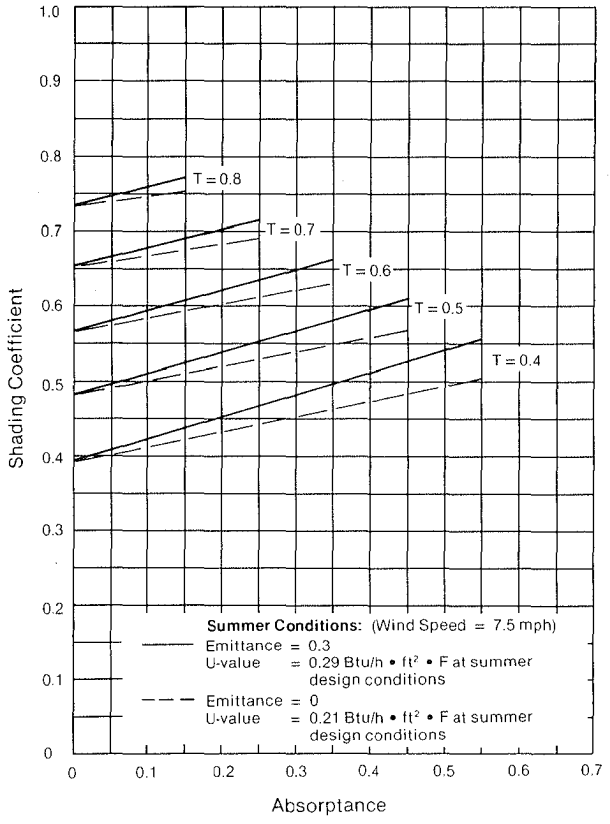
Shading Coefficient
Absorptance
T = 0.8
T = 0.7
T = 0.6
T = 0.5
T = 0.4
T = 0.3
T = 0.2
Summer Conditions: (Wind Speed = 7.5 mph)
Emittance = 0.3
U-value = 0.40 Btu/h • ft² • F at summer design conditions
Emittance = 0
U-value = 0.26 Btu/h • ft² • F at summer design conditions

Fig. 23 Shading Coefficient for Double Glazing with Low Emittance Coating on Surface 2

For double and triple glazing with low-emittance coatings, the SC varies as a function of glazing transmittance, absorptance, and the glazing surface to which the low emittance coating is applied. For summer conditions, SC is given as a function of transmittance and absorptance in Figure 23 for double glazing with low-emittance coatings on the No. 2 surface (measured from the outside) and in Figure 24, for triple glazing with low emittance coatings on the No. 4 surface. Similarly, under winter conditions, SC is given in Figure 25 for double glazing with coatings on the No. 3 surface and in Figure 26, for triple glazings, again on No. 3 surfaces. In all figures, the transmittance and absorptance values are for the low-emittance coating and glass or plastic substrate only (the SC values are for the complete glazing system). The remaining light(s) of glass making up the window unit are assumed clear and 0.125 in. thick.

Low-emittance coatings used in windows with bronze, gray, or blue-green glass produce different shading coefficients. Moderate changes in design temperature conditions, gap widths (assumed to be 0.5 in.), exterior and interior film coefficients, and the overall U-factor do not significantly change the SC for the given transmittance, absorptance, and emittance. SC for the actual coating emittance can be found in interpolating between the emittance values of 0 and 0.3 (Rubin 1984, Selkowitz 1979).

Shading coefficients for uncoated single-glazing materials (plastic sheet as well as glass) with transmittances other than those cited in Table 20 can be estimated from Figure 21, since SC is virtually a linear function of the normal incidence transmittance. The tabulated values can be interpolated for insulating glass when the inner light is clear sheet or plate glass. When heat-absorbing glass is used in double glazing in cooling dominated climates, it should be installed in the outer light, so that the absorbed heat can be more readily dissipated to the atmosphere.



Shading Coefficient
Absorptance
T = 0.8
T = 0.7
T = 0.6
T = 0.5
T = 0.4
Summer Conditions: (Wind Speed = 7.5 mph)
Emittance = 0.3

Emittance = 0
U-value = 0.21 Btu/h • ft² • F at summer design conditions

Fig. 24 Shading Coefficient for Triple Glazing (Glass-Plastic-Glass) with Low-Emittance Coating on Surface 4

When indoor shading devices are used with glass fenestration, small differences in glass properties become unimportant. Consequently, the wide range of glasses listed in Table 11, Part A, can be expanded into four classes; the insulating glasses in Table 11, Part B, into two classes.

Airflow Windows

If properly managed, airflow between panes of a double-glazed window can improve fenestration performance. In normal use, a venetian blind is located between the glazing layers. Ventilation air from the room enters the double-glazed cavity, flows over the blind, and is, in some designs, exhausted from the building or returned through the ducts to the central HVAC system. In cold weather, the window acts as a heat exchanger when sunlit, so that the inner glass temperature nearly equals the room air temperature and improves thermal comfort.

The apparent conductance across the inner glazing is very low, but this is misleading since additional heat is lost to the outdoors from the moving airstream in the window cavity. During sunny winter days, the blind acts as a solar air collector; heat removed by the moving air can be used elsewhere in the building. In the summer, the window can have a very low shading coefficient if the blinds are appropriately placed, since the majority of solar gains are removed from the window. These systems can control window heat transfer under many different operating conditions. Sodergren and Bostrom (1971) and Brandle and Boehm (1982) give details on airflow or exhaust windows.

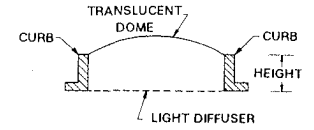
Domed Skylights

Solar and total heat gains for domed skylights can be determined by the same procedure used for windows. The SHGF values for such calculations should be consistent with the dome orientations. For horizontal roofs, Tables 12 through 18 give approximate SHGF values. For sloping roofs, an approximate SHGF can be found from SHGF = $E_t/1.15$, where E_t = total solar irradiation on the sloping surface. Table 21 gives SC for plastic domed skylights. Manufacturers' literature has further details.

Glass Block Walls

Glass block provides light transmission in exterior walls when optical clarity for view is not desired. Table 22 describes the glass block patterns discussed in the following text and gives shading

Table 21 Shading Coefficients for Domed Horizontal Skylights



Dome	Light Diffuser (Translucent)	Curb Height, in.	Curb Width to Height Ratio	Shading Coefficient

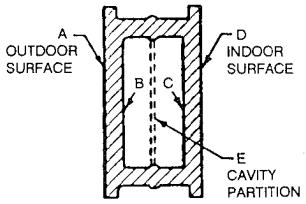
Table 22 Shading Coefficients and U-Factors for Standard Hollow Glass Block Wall Panels

Type of Glass Block[a]	Description of Glass Block	Shading Coefficient[b] Panels[c] in Sun	Panels[d] in Shade (N, NW, W, SW)	U-Factor,[e] Btu/h·ft²·°F
Type I	Glass colorless or aqua A, D: Smooth B, C: Smooth or wide ribs, or flutes horizontal or vertical, or shallow configuration E: None	0.65	0.40	0.51
Type IA	Same as Type I except ceramic enamel on A	0.27	0.20	0.51
Type II	Same as Type I except glass fiber screen partition E	0.44	0.34	0.48
Type III	Glass colorless or aqua A, D: Narrow vertical ribs or flutes. B, C: Horizontal light-diffusing prisms, or horizontal light-directing prisms E: Glass fiber screen	0.33	0.27	0.48
Type IIIA	Same as Type III except E: Glass fiber screen with green ceramic spray coating or glass fiber screen and gray glass or glass fiber screen with light-selecting prisms	0.25	0.18	0.48
Type IV	Same as Type I except reflective oxide coating on A	0.16	0.12	0.51



[a]All values are for 7 3/4 by 7 3/4 by 3 7/8 in. block, set in light-colored mortar. For 11 3/4 by 11 3/4 by 3 7/8 in. block, increase coefficients by 15%, and for 5 3/4 by 5 3/4 by 3 7/8 in. block reduce coefficents by 15%.
[b]Shading coefficients are applied to heat gain factors for one hour earlier than the load calculation time to allow for heat storage in the panel.
[c]Shading coefficients are for peak load condition, but provide a close approximation for other conditions.
[d]For NE, E, and SE panels in shade, add 50% to the values listed for panels in the shade.
[e]Values shown are the same for all size block.

coefficients to be applied to solar heat gain factors from Tables 12 through 18 so that instantaneous solar heat gains can be calculated.

Convection and low-temperature radiation heat gain for all hollow glass block panels fall within a narrow range. Differences in shading coefficients are largely the result of differences in the transmittance of the glass blocks for solar radiation. Shading coefficients for any particular glass block pattern vary depending on orientation and time of day. The SC for western exposures in the morning (in the shade) is depressed because of the heat storage within the block, whereas the SC for eastern exposures in the afternoon (in the shade) is elevated as the stored heat is dissipated. Time lag effects from heat storage are estimated by using SHGFs and air-to-air temperature differences for one hour earlier than the time for which the load calculation is made.

Calorimeter tests of Type IA glass block showed little difference in solar heat gains between glass block with either black or white ceramic enamel on the exterior of the block. Because white and black ceramic enamel surfaces represent the two extremes for reflecting or absorbing solar energy, glass block with enamel surfaces of other colors should have shading coefficients between these values.

GLAZING MATERIALS

PLASTIC MATERIALS FOR GLAZING

Generally, the factors outlined for glass apply also to glazing materials such as acrylic or other plastic panels. If the solar transmittance, absorptance, and reflectance are known, a shading coefficient can be calculated in the same way it is for glass. These properties can be obtained from the manufacturer or determined by simple laboratory tests. Both ASHRAE and ASTM have developed standards for performing these tests.

Table 23 lists solar optical properties of typical plastic materials. Plastic panels are available with transmittance values from 10 to 92% and reflectance values from 4 to over 60%. Emittances for acrylic, polystyrene, and polycarbonate glazing all range between 0.88 and 0.92. Plastics are available in translucent and transparent form; some are corrugated. Many tints (colors) are also available.

Figure 17 can be used to obtain an approximate SC for single panels of low reflectivity. Where shading is involved, the SC for a glass of similar solar optical properties can be used. The plastic manufacturer has the engineering data.

In selecting plastic panels for glazing, possible deterioration from the sun, expansion and contraction because of temperature extremes, and possible damage from abrasion are concerns.

Table 23 Solar Optical Properties and Shading Coefficients of Transparent Plastic Sheeting
(Burkhardt 1975, 1976)

CHOOSING GLASS FOR BUILDINGS

The choice of glass as a glazing material, should be based on (1) light transmittance and daylight use, (2) occupant comfort, (3) sound reduction, (4) strength (deflection under load), (5)safety (security), (6) life cycle costs, and (7) aesthetics. In many respects, these factors and the thermal performance of glass are related.

Light transmittance and daylight use. When daylight is to be the primary lighting system, the minimum expected daylight in the building must be calculated for the building performance cycle and integrated into the lighting calculations. IES (1979) gives daylight design and calculation procedures. In some glazing applications, such as artists' studios and showrooms, maximum transmittance may be required for adequate daylighting of the interior. Regular clear glass, produced by float, plate, or sheet process, may be the logical choice.

When daylight is a supplementary light source, the electric lighting can be designed independently of the daylight system. But adequate switching must be included in the electric distribution to substitute available daylight for electric lighting by automatic or prescribed manual control. Photosensitive controls automatically adjust shading devices to provide uniform illumination and reduce energy consumption. Manual control is less effective.

Buildings with large areas of glass usually have insulating glass units with clear, tinted, or reflective-film. The tinted and reflecting units reduce the brightness contrast between windows and other room surfaces and provide a relatively glare-free environment for most daylight conditions.

Tables 11 and 24 list typical solar energy transmittances and daylight transmittances for various glass types. Manufacturers' literature have more appropriate values.

The color of glass chosen for a building depends largely on where and how it is used. For commercial building lobbies, showroom windows, and other areas where maximum visibility from exterior to interior is required, regular clear glass is generally best. For other glass areas, a tinted glass may best complement the interior colors. Bronze, gray, and reflective-film glasses also give some privacy to building occupants during daylight hours. Patterned, etched, or sandblasted glass that diffuses lighting is available.

Occupant comfort and acceptance. Tinted and reflective film glasses reduce summer heat gain as well as winter heat loss. Insulating glass units, especially reflective-film types, also reduce radiation heat transfer between building occupants and window areas, thereby providing greater year-round comfort. ASHRAE *Standard* 55 requires that the variations in radiant temperature be limited to achieve a minimum level of occupant comfort. For buildings with sliding glass doors or equivalent size glazing areas, the net effect is to require double-glazing in all climates where the winter design temperature is less than 45 °F. Drafts from cold glass surfaces are also reduced in cold weather, and higher relative humidities can be maintained without condensation. Such high performance glasses often reduce cooling load 15 to 30% below that with clear glass (Rudoy and Duran 1975). Clear insulating glass with light-colored continuous interior shading, or particularly with exterior shading, can reduce fenestration cooling load substantially.

Table 24 Daylight Transmittance for Various Types of Glass

Type of Glass	Visible Transmittance
1/8-in. regular sheet or float glass	0.86 to 0.91
1/8-in. gray sheet	0.31 to 0.71
3/16-in. gray sheet	0.61
7/32-in. gray sheet	0.14 to 0.56
1/4-in. gray sheet	0.52
1/4-in. green/float glass	0.75
1/4-in. gray plate glass	0.44
1/4-in. bronze plate glass	0.49
1/2-in. gray plate glass	0.21
1/2-in. bronze plate glass	0.25
Coated glasses (single, laminated, insulating)	0.07 to 0.50

Sound reduction. Proper acoustical treatment of exterior walls can decrease noise levels in certain areas. The airtightness of a wall is the primary factor to consider in reducing sound transmission from the exterior. Once walls and windows are tight, the choice of glass and draperies becomes important. Draperies do not prevent sound from coming through the fenestration; they act as an absorber for sound that does penetrate. Table 25 lists average sound transmission losses for various types of glass. These averages apply for the frequency range of 125 to 4000 Hz and were determined by tests based on ASTM *Standard* E 90.1. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* has further details.

Strength and safety. In addition to its thermal, visual, and aesthetic functions, glass for building exteriors must also structurally perform. Wind loads are specified in most building codes, and these requirements may be adequate for many structures. However, detailed wind tunnel tests should be run for tall or unusually shaped buildings and for buildings where the surroundings create unusual wind patterns. Alternative loading conditions should be chosen in developing design specifications when wind load tests suggest wind loading conditions different from those shown in Figure 27. All manufacturers do not agree on the values presented here; for specific information, consult the glass manufacturer.

Figure 27 shows the relationship between size, thickness, and strength of annealed glass using a design factor of 2.5 (average breaking pressure divided by 2.5). The graphs are based on actual tests to destruction, in which the glass was exposed to uniform loads increased in increments and held static for one minute. Figure 31 applies to rectangular lights of glass, with length-to-width ratios of not more than 5:1, firmly supported on all four edges. To determine the uniform load of nonannealed glass held on four sides, use the appropriate multiplying factor listed in Table 26.

Thermal expansion and contraction of glass can cause breakage or produce openings in the glazing system causing greater air infiltration. Tinted and reflective-type glasses are especially vulnerable to thermal stress. The manufacturer should provide information on thermal stress performance.

Building codes may require glass in certain positions to perform with certain breakage characteristics, which can be satisfied by tempered, laminated, or wired glass. In this case, glass should meet *Federal Standard* 16 CRF 1201 or other appropriate breakage performance requirements.

Table 25 Sound Transmittance Loss for Various Types of Glass

Type of Glass	Sound Transmittance Loss, db

1-in. insulating glass	32
1/2-in. laminated glass (9/20-in. plastic interlayer)	34
Insulating glass, 6-in. air space, 1/4-in. plate or float glass	40

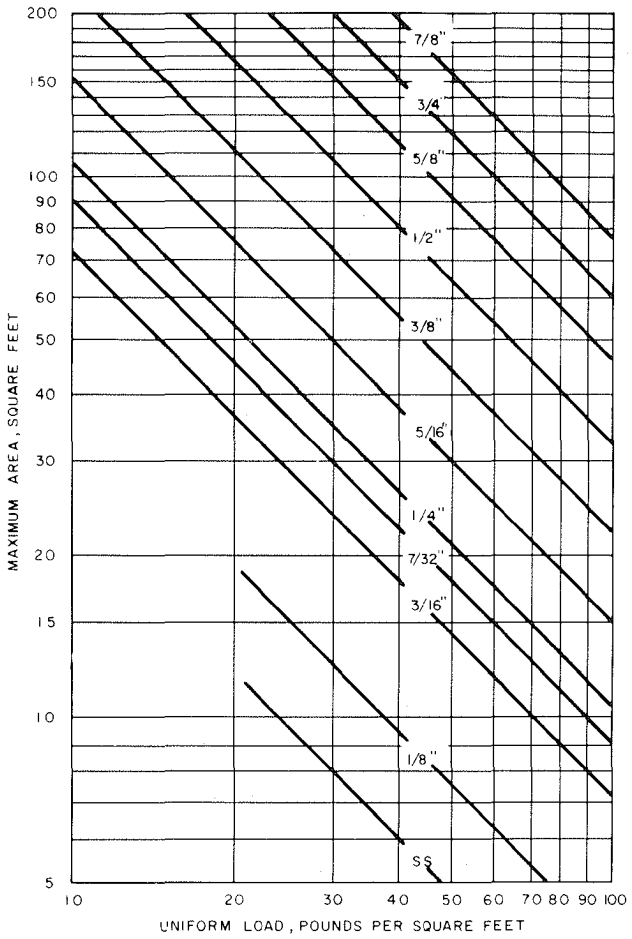

Fig. 27 Design Thickness for Annealed Glass

Table 26 Multiplier for Other than Annealed Glass

Type of Glass	Multiplier	Type of Glass	Multiplier
Tempered	4.0	Rough plate	1.0
Heat strengthened	2.0	Laminated	0.6
Double glazed	1.5	Wired	0.5

Note: Sandblasting significantly weakens glass and can reduce its strength by 60% or more. Sandblasted glass should not be used for exterior glazing.

Life-cycle costs. Alternative building shells should be compared to assure satisfactory energy use and total energy budget compliance, if required. ASHRAE *Standard* 90.1-1989 should be used as a starting point. A life-cycle cost model should be developed for each system considered, see Chapter 33 of the 1991 ASHRAE *Handbook—Applications.*

SHADING

EXTERIOR SHADING

The most effective way to reduce the solar load on fenestration is to intercept direct radiation from the sun before it reaches the glass. Windows fully shaded from the outside will reduce solar heat gain as much as 80%. In one way or another, fenestration can be shaded by roof overhangs, vertical and horizontal architectural projections, awnings, heavily proportioned exterior louvers, insect or shading screens, patterned screens having a weave designed for sunlight interception, or sun screens of narrow fixed louvers. In all exterior shading structures, the air must move freely to carry away heat absorbed by the shading and glazing materials. See manufacturer's instructions regarding proper installation for achieving expected performance by providing suitable free convection ventilation between shading and glazing. Also, consider the geometry of the structures relative to changing sun position to determine the times and quantities of direct sunlight penetration. Detailed discussions of the effectiveness of various outside shading devices are given in Pennington (1968), Yellott (1972), and Ewing and Yellott (1976).

Louvers and Sunshades

The ability of horizontal panels or louvers to intercept the direct component of solar radiation depends on their geometry and the profile or shadow-line angle Ω (Figure 27), defined as the angular difference between a horizontal plane and a plane tilted about a horizontal axis in the plane of the fenestration until it includes the sun. The profile angle can be calculated by

$$\tan \Omega = \tan \beta / \cos \gamma \qquad (44)$$

For slat-type sunshades, the transmitted solar radiation consists of straight-through and transmitted-through components. When the profile angle Ω is above the cutoff angle (see Figure 28), straight-through transmission of direct radiation is completely eliminated, but the transmitted diffuse and the reflected-through components remain. Their magnitude depends largely on the reflectance of the sunshade surfaces and of exterior objects.

Narrow horizontal louvers fabricated in conventional width-spacing ratios and framed as window screens, retain their shading characteristics, while gaining in effective transparency (view) by eliminating the coarse striation pattern of wide louvers. Table 27 gives shading coefficients (SC) for several types of louvered sun screens. Commercially available sun screens completely exclude direct solar radiation when the profile angle exceeds approximately 26° (Groups 1, 2, and 5) or 40° (Groups 3, 4, and 6). Group designations are defined in the table footnote.

Table 27 Shading Coefficients for Louvered Sun Screens

Profile Angle	Group 1		Group 2		Group 3		Group 4		Group 5		Group 6	
	Transmittance	SC	Transmittance	SC	Transmittance	SC	Transmittance	SC	Transmittance	SC	Transmittance	SC
10°	0.23	0.35	0.25	0.33	0.40	0.51	0.48	0.59	0.15	0.27	0.26	0.45
20°	0.06	0.17	0.14	0.23	0.32	0.42	0.39	0.50	0.04	0.11	0.20	0.35
30°	0.04	0.15	0.12	0.21	0.21	0.31	0.28	0.38	0.03	0.10	0.13	0.26
≥ 40°	0.04	0.15	0.11	0.20	0.07	0.18	0.20	0.30	0.03	0.10	0.04	0.13

Group 1. Black, width over spacing ratio 1.15/1; 23 louvers/in. Group 2. Light color; high reflectance, otherwise same as Group 1. Group 3. Black or dark color; w/s ratio 0.85/1; 17 louvers/in. Group 4. Light color or unpainted aluminum; high reflectance; otherwise same as Group 3. Group 5. Same as Group 1, except two lights of 0.25 in. clear glass with 0.5 in. air space. Group 6. Same as Group 3, except two lights of 0.25 in. clear glass with 0.5 in. air space. U-value = 0.85 Btu/h · ft^2 · °F for all groups when used with single glazing.

Roof Overhangs; Horizontal and Vertical Projections

In the northern hemisphere, horizontal projections can considerably reduce solar heat gain on south, southeast, and southwest exposures during late spring, summer, and early fall. On east and west exposures during the entire year, and on southerly exposures in winter, the solar altitude is generally so low that to be effective horizontal projections must be excessively long.

The shadow width S_W and shadow height S_H (Figure 30), produced by the vertical and horizontal projections (P_V and P_W), respectively, can be calculated using the solar surface azimuth γ and the horizontal profile angle Ω determined by Equation (44).

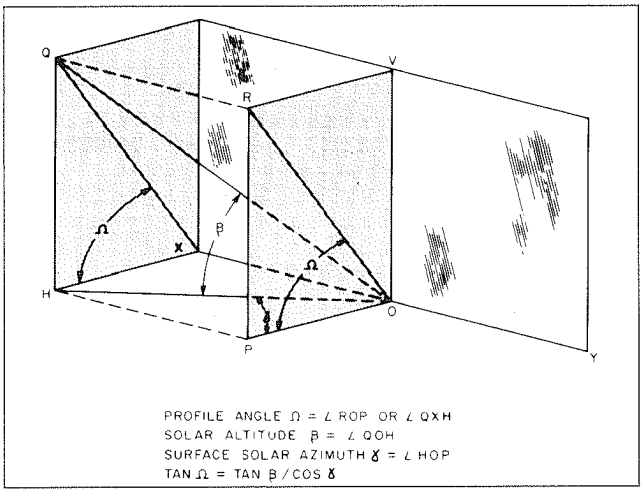

Fig. 28 Profile Angle for South-Facing Slat-Type Sunshades

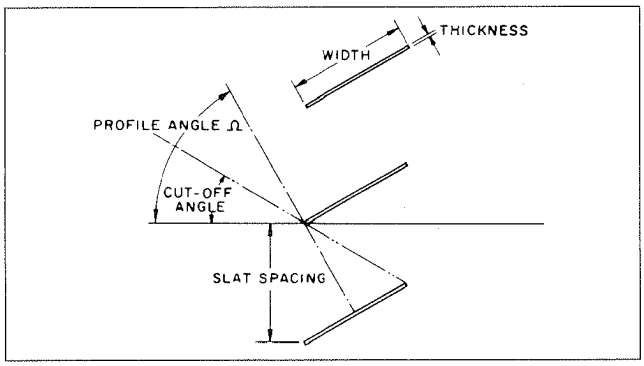

Fig. 29 Geometry of Slat-Type Sunshades

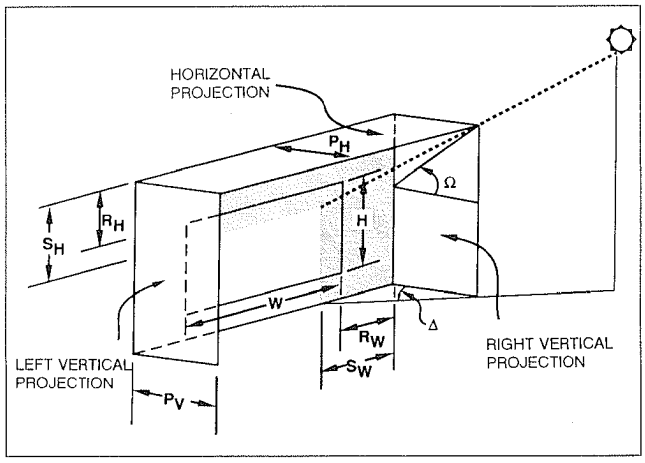

Fig. 30 Vertical and Horizontal Projections and Related Profile Angles for Vertical Surface Containing Fenestration System

$$S_W = P_V |\tan \gamma| \quad (45)$$

$$S_H = P_H \tan \Omega \quad (46)$$

Note: When the solar surface azimuth γ is greater than 90° and less than 270°, the window is completely in the shade; thus, $S_W = W + R_W$ and $A_{SL} = 0$.

The sunlit A_{SL} and shaded A_{SH} area of the window is variable during the day and can be calculated for each moment using the following relations (see Figure 30)

$$A_{SL} = [W - (S_W - R_W)][H - S_H - R_H)] \quad (47)$$

$$A_{SH} = A - A_{SL} \quad (48)$$

where A is total window area.

Example 10 A window in the southwest wall of a building at 40°N latitude at 1500 on July 21 is 34.5 in. wide and 58.5 in. high. The depth of the horizontal and vertical projections are 6 in., located 3 in. beyond the edges of the window.

Part A. Find the sunlit and shaded area of the window.

Part B. Find the depth of projections needed to fully shade the window.

Solution

Part A. The wall azimuth ψ for a southwest wall is +45° (Table 8). The solar azimuth ϕ can be calculated using Equation (8b). At 1500, $H = 0.25 \times 180 = 45°$; from Table 7, for July 21, $\delta = 20.6°$.

Find the solar altitude β using Equation (8a)

$$\sin \beta = \cos(40)\cos(20.6)\cos(45) + \sin(40)\sin(20.6)$$
$$\beta = 47.2°$$

Find the solar azimuth ϕ using Equation (8b)

$$\cos \phi = [\sin(47.2)\sin(40) - \sin(20.6)]/[\cos(47.2)\cos(40)]$$
$$\phi = 76.7°$$

Thus, $\gamma = 76.7 - 45 = 31.7°$

Using Equation (45), the width of the vertical projection shadow is

$$S_W = 6 |\tan 31.7| = 3.71 \text{ in.}$$

Using Equation (44), the profile angle for the horizontal projection is

$$\tan \Omega = \tan(47.2)/\cos(31.7)$$
$$\Omega = 51.8°$$

Using Equation (46), the height of the horizontal projection shadow is

$$S_H = 6 \tan 51.8 = 7.62 \text{ in.}$$

Using Equations (47) and (48), the sunlit and shaded area of the window are now

$$A_{SL} = [34.5 - (3.71 - 3)]\,[58.5 - (7.62 - 3)]/144 = 12.6 \text{ ft}^2$$
$$A_{sh} = (34.5 \times 58.5/144) - 12.6 = 1.4 \text{ ft}^2$$

Part B. The shadow length necessary to fully shade the given window $S_{H(fs)}$ and $S_{W(fs)}$ from the horizontal and vertical projection are given by (see Figure 30)

$$S_{H(fs)} = 58.5 + 3 = 61.5 \text{ in.}$$

$$S_{W(fs)} = 34.5 + 3 = 37.5 \text{ in.}$$

Thus, using Equations (45) and (46)

$$P_{H(fs)} = 61.5 \cot(51.8) = 48.4 \text{ in.}$$

$$P_{W(fs)} = 37.5 \left|\cot(31.7)\right| = 60.7 \text{ in.}$$

For this example, since both the horizontal and vertical projections do not need to fully shade the window, a horizontal projection of 48.4 in. is satisfactory. Also, to accurately analyze the influence of external shadowing by projections, an hour-by-hour calculation must be performed over the periods of the year for which shadowing is desired.

Partially Shaded Windows

All solar heat gain data in this section are based on the sunlit area of the glass itself. For actual windows, the sunlit glass area is likely to be significantly less than the total window area, and the effect of external shadowing as well as the effect of the opaque areas must be considered.

Besides the horizontal and vertical projections, external shade can be produced by the mullions and the transom. The shaded area varies continuously throughout the day, but it can be estimated readily by treating the mullions and transom as vertical and horizontal projections and applying Equation (46).

The solar heat gain factors (defined in the section Simplified Methods for Predicting Heat Transfer through Fenestration) through a partially shaded window, can be estimated using

$$\text{SHGF} = E_D (A_{SL}/A) + E_d$$

The diffuse component E_d can be found using the SHGF values (Tables 12 through 18) for the nearest facade not receiving direct sunlight. The direct component of solar radiation can be estimated by subtracting the diffuse component E_d from the SHGF values (Tables 12 through 18) for an unshaded window.

The solar heat gain for the entire window is then

$$\text{Solar heat gain} = (\text{SC}) \times (\text{SHGF}) \times (A) \qquad (50)$$

Example 11. Find the solar heat gain through the window given in Example 10 assuming that the window consists of 0.25 in. clear plate glass.

Solution: At 1500, the SHGF for an unshaded window in a southwest wall is 170 Btu/(h · ft²) of which the diffuse component is 31 Btu/(h · ft²).

$$\text{SHGF} = \frac{12.64}{14.02}(139 + 31) = 156.3 \text{ Btu/(h} \cdot \text{ft}^2\text{)}$$

The SC for 0.25 in. plate glass (assuming in this example that one-half the absorbed energy is dissipated to the room air) is 0.97; thus, the solar heat gain through the window is

$$\text{Solar heat gain} = 0.97 \times 156.3 \times 14.02 = 2125.6 \text{ Btu/h}$$

Equations for Computer Calculations of External Shadowing of Inclined Surfaces

Incidence angle: $\theta = \cos^{-1}(\cos\beta\cos\gamma\sin\Sigma + \sin\beta\cos\Sigma)$

Vertical surface $\theta_V = \cos^{-1}(\cos\beta\cos\gamma)$

Horizontal surface $\theta_H = \cos^{-1}(\sin\beta)$

Vertical projection profile angle:

$$\Delta = \tan^{-1}\left(\frac{\sin\gamma\cos\beta}{\cos\theta}\right);\ |2| < 90°$$

For $\theta > 90°$ $A_{SL} = 0$ and $A_{SH} = A$

Vertical surface $\Delta_V = \tan^{-1}(\gamma)$; $|\gamma| < 90°$ and $|\gamma| > 270°$

Horizontal surface $\Delta_H = \tan^{-1}\left(\frac{\sin\gamma}{\tan\beta}\right)$; for all γ

Horizontal projection profile:

Angle: $\Omega = \tan^{-1}\left(\frac{\sin\beta\sin\Sigma - \cos\beta\cos\gamma\cos\Sigma}{\cos\theta}\right)$; $|\theta| < 90°$

Vertical surface $\Omega_V = \tan^{-1}\left(\frac{\tan\beta}{\cos\gamma}\right)$; $|\gamma| < 90°$ and $|\gamma| > 270°$

Horizontal surface $\Omega_H = \tan^{-1}\left(-\frac{\cos\gamma}{\tan\beta}\right)$; $90° < |\gamma| < 270°$

Length of shadow from vertical projection:

$$S_W = P_V \left|\tan\Delta\right|$$

Length of shadow from horizontal projection:

$$S_H = P_H \left|\tan\Omega\right|$$

Sunlit area of the window:

$$A_{SL} = [W - (S_W - R_W)]\,[H - (S_H - R_H)]$$

Shaded area of the window:

$$A_{SH} = A - A_{SL}$$

where

ϕ = solar azimuth
β = solar altitude
γ = solar surface azimuth
Σ = surface tilt angle
P_V = vertical projection depth
P_H = horizontal projection depth
W = window width
H = window height
R_W = width of opaque surface between window and vertical projection
R_H = height of opaque surface between window and horizontal projection
A = total projected area of the window
θ = angle of incidence
Ω = horizontal projection profile angle
Δ = vertical projection profile angle

INDOOR SHADING DEVICES

Venetian Blinds and Roller Shades

Most fenestration has some type of internal shading to provide privacy and aesthetic effects, as well as to give varying degrees of sun control (Ozisik and Schutrum 1960). The SC values for typical internal shading are given in Tables 28, 29, and 30. The effectiveness of any internal shading device depends on its ability to reflect incoming solar radiation back through the fenestration before it can be absorbed and converted into heat within the building. Table 31 lists approximate values of solar-optical properties for the typical indoor shading devices described in Tables 28, 29, and 30.

Table 28 Shading Coefficients for Single Glass with Indoor Shading by Venetian Blinds or Roller Shades

Type of Glass	Nominal Thickness[a], in.	Solar Transmittance[b]	Type of Shading: Venetian Blinds Medium	Venetian Blinds Light	Roller Shade Opaque Dark	Roller Shade Opaque White	Roller Shade Translucent Light

Heat-absorbing[b] out, Clear in				Shade in contact with glass or shade separated from glass by air space.	0.28	0.30	0.37
	1/4 in.	0.46	0.80	Shade in contact with glass-voids filled with plastic.	—	—	0.41

[a]Refer to manufacturers' literature for exact values.
[b]Refers to grey, bronze and green tinted heat-absorbing glass.

Table 31 Properties of Representative Indoor Shading Devices Shown in Tables 28, 29, and 30

Indoor Shade	Solar-Optical Properties (Normal Incidence) Trans.	Reflect.	Absorp.
Venetian blinds[a] (ratio of slat width to slat spacing 1.2, slat angle 45°)			
Light colored slat	0.05	0.55	0.40
Medium colored slat	0.05	0.35	0.60
Vertical blinds			
White louvers	0.00	0.77	0.23
Roller shades			
Light shades (translucent)	0.25	0.60	0.15
White shade (opaque)	0.00	0.65	0.35
Dark colored shade (opaque)	0.00	0.20	0.80

[a]Values in this table and preceding tables are based on horizontal venetian blinds. However, tests show that these values can be used for vertical blinds with good accuracy.

The values in Table 28 apply both to sunlit fenestration and fenestration on the shaded side of the building. The values are similar in both cases because shades generally are open on shaded exposures. The tabulated values apply specifically to horizontal venetian blinds but are usable for vertical blinds when adjusted so that no direct solar radiation can enter through them.

Table 29 gives SCs for venetian blinds and roller shades used with insulating glass. The first row applies to windows in which both lights are high-transmittance glass; the second applies when the outer light is heat-absorbing and the inner light is clear glass.

Because of the wide variety of glass available, the manufacturer should be consulted for specific data. The SC with no interior shading is included as a reference point for each classification. Note that the energy benefit of a shade decreases as the SC of the unshaded glass decreases. Similarly, the flexibility of the fenestration system decreases as the SC decreases, due to the low transmittances and the inability of the occupant to change this factor.

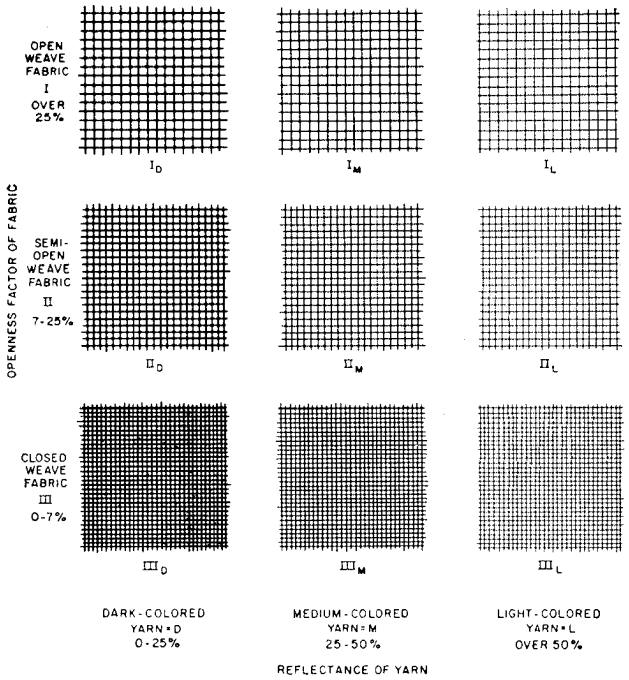
Draperies

Draperies reduce heating and cooling loads, depending on the type and the use by the occupant. Rudoy and Duran (1975) found annual reductions between 5 and 20%.

The solar optical properties of drapery fabrics can be determined accurately by laboratory tests (Yellott 1963), and manufacturers can usually supply solar transmittance and reflectance values of their products. In addition to these properties, the openness factor (ratio of the open area between the fibers to the total area of the fabric) is a useful property that can be measured exactly (Keyes 1967, Pennington and Moore 1967). It can also be estimated by inspection, since the human eye can readily distinguish between tightly woven fabrics that permit little direct radiation to pass between the fibers and loosely woven fabrics which allow the sun's rays to pass freely.

Drapery fabrics can be classified in terms of their solar-optical properties as having specific values of fabric transmittance and reflectance. Fabric reflectance is the major factor in determining the ability of a fabric to reduce solar heat gain. Based on their appearance, draperies can also be classified by yarn color as dark, medium, and light; and by weave as closed, semiopen, and open. The apparent color of a fabric is determined by the reflectance of the yarn itself. The figure in Table 32 shows yarn reflectance. Figure 31 classifies drapery fabrics into nine types, rated by openness and yarn reflectances.

Figure 31, with the aid of Table 32, guides in estimating the probable SC for a fabric-glass combination when the solar-optical properties are unknown. Whenever possible, fabric reflectance and transmittance values should be obtained from the manufacturer, which permits more accurate SC estimates to be made. Visual



Note: Classes may be approximated by eye. With closed fabrics, no objects are visible through the material, but large light or dark areas may show. Semiopen fabrics do not permit details to be seen, and large objects are clearly defined. Open fabrics allow details to be seen, and the general view is relatively clear with no confusion of vision. The yarn color or shade of light or dark may be observed to determine whether the fabric is light, medium, or dark.

Fig. 31 Classification of Drapery Fabrics

estimations of openness and yarn reflectance, interpreted through Table 32, are valuable in judging the effectiveness of drapes for (1) protection from excessive radiant energy from either sunlight or sun-heated glass, (2) brightness control, (3) providing either outward view or privacy, and (4) sound control.

Table 32 applies to glass and a single drape hung with 100% fullness (drapery width is twice the width of the draped area). If the drapery is hung flat, like a window shade, a different SC applies; with a low transmittance and high reflectance, the SC is appreciably lower. As an extreme example, a flat opaque drapery having an aluminized or similar coating with reflectance of 0.80, in combination with 0.25-in. clear glass, has an SC of 0.18, as compared with 0.32 that can be extrapolated from Table 32 for this material in draped form. Pennington and Moore (1967) explain the effect of folding drapery materials to provide 100% fullness, and describe a method for calculating SC when materials are used flat.

Example 12. A drape with 100% fullness, having a fabric transmittance of 0.20 and a fabric reflectance of 0.40, is used with 0.25-in. glass. What SC should be used?

Solution: From the figure in Table 32, the 0.20 and 0.40 intersection is nearest line F. Table 32 assigns SC 0.55 to column F for 0.25-in. clear single glass. Interpolate if necessary; see notes for other uses.

Example 13. For the same drapery as in Example 12, the incident angle for which the SC is desired is 30°. What SC should be used?

Solution: Add 5% to the value found in Example 12. Thus,

$$SC = (1 + 0.05)\,0.55 = 0.58$$

Example 14. Determine the Fabric Designator for a fabric having an openness factor of 0.10 and a yarn reflectance of 0.60.

Solution: On the figure in Table 32, these lines intersect in the area of Designator II_L. Refer also to Figure 31. Fabric is semiopen and light in color. Additional information: probable fabric reflectance is 0.50, and fabric transmittance is 0.35.

Shading Coefficient Index Letter

Notes:
1. Shading coefficients are for draped fabrics.
2. Other properties are for fabrics in flat orientation.
3. Use fabric reflectance and transmittance to obtain accurate shading coefficients.
4. Use openness and yarn reflectance or openness and fabric reflectance to obtain the various environmental characteristics, or to obtain approximate shading coefficients.

Classification of Fabrics

I = Open weave
II = Semiopen weave
III = Closed weave

D = Dark color
M = Medium color
L = Light color

To obtain fabric designator (III_L, I_M, etc.). Using either (1) Fabric Transmittance and Fabric Reflectance coordinates, or (2) Openness and Yarn Reflectance coordinates, find a point on the chart and note the designator for that area. If properties are not known, the classification may be approximated by eye as described in the note in Figure 31. Table 33 lists appropriate classifications for various applications.

To obtain shading coefficient (SC). (1) Locate drapery fabric as a point using its known properties, or approximate using its fabric classification designator. For accuracy, use fabric transmittance and fabric reflectance; (2) follow diagonal SC lines to lettered columns in the table. Find SC on line with glazing used. For example, SC is 0.45 for 0.25-in. clear single glass with III_L drapery (Column H).

Note: Shading coefficients are for 45° incident angle. For 30° or less, add 5% to the number found in the table.

VISUAL AND THERMAL CONTROLS

The ideal fenestration system permits optimum light, heat, ventilation, and visibility; minimizes moisture and sound transfer between the exterior and the interior; and produces a satisfactory physiological and psychological environment. The controls of an optimum system react to varying climatological and occupant demands. Fixed controls may have operations or cost advantages or both but do not react to physical and psychological variations. Variable controls are, therefore, more effective in energy conservation and environmental satisfaction.

Operational Effectiveness of Shading Devices

Shading devices vary in their operational effectiveness. Some devices such as overhangs and tinted glazings do not require operation, have long life expectancies, and do not degrade significantly over their effective life. Other types of shading devices, especially operable interior shades, may have reduced effectiveness due to less than optimal operation and degradation of effectiveness over time. It is important to evaluate operational effectiveness when considering the actual heat rejection potential of shading devices.

The performance of shading devices for the reduction of peak cooling loads and annual energy use should account for operational effectiveness or reliability in actual operation. Passive devices, such as architectural elements and glazing tinting, are considered 100% effective in operation. Glazing coatings and adherent films may degrade over time. Shade screens are removable and may be assumed to be operated seasonally but in any given population of users some will remain in place all year long and some will not be installed or removed at optimum times. Automated shading devices controlled for optimum thermal operation are considered more effective than manual devices, but controls require ongoing maintenance. Automated shading devices may also be operated for nonthermal purposes such as glare and daylighting optimization which may reduce thermal effectiveness. Manually operated devices will be subject to wide variation in use effectiveness, and this diversity in effective use should be considered when evaluating performance.

Indoor Shading Devices

Thermal comfort of occupants within the glazed space is paramount. Other factors (see Table 32 and Figure 31) include the following.

Radiant energy protection. Unshaded windows become sources of radiant heat by transmitting short-wave solar radiation and by emitting long-wave radiation to dissipate some of the absorbed solar energy. In winter, glass temperatures usually fall below room air temperature, which may produce thermal discomfort to occupants near the fenestration. In summer, individuals seated near the unshaded window may experience discomfort from both direct solar rays and long-wave radiation emitted by sunheated glass. In winter, loss of heat by radiation to cold glass can also cause discomfort. Tightly woven, highly reflective drapes minimize such discomfort; drapes with high openness factors are less effective because they permit short-wave and long-wave radiation to pass more freely. Light-colored shading devices with maximum total surface usually provide the best protection, since they absorb less heat and tend to lose heat readily by convection to the conditioned air.

Outward vision. Outward vision is normally desirable in both business and living spaces. Open-weave, dark-colored fabrics of uniform pattern permit maximum outward vision, while uneven pattern weaves reduce the ability to see out. A semi-open weave modifies the view without completely obscuring the outdoors. Tightly woven fabrics block off outward vision completely.

Privacy. Venetian blinds, either vertical or horizontal, can be adjusted and, when completely closed, afford full privacy. When draperies are closed, the degree of privacy is determined by their color and tightness of weave, and the source of the principal illumination. To obscure the view so completely that not even shadows or silhouettes can be detected, fully opaque materials are used.

Brightness control. Visual comfort is essential in many occupied areas, and freedom from glare is an important factor in performing tasks. Direct sunlight must not strike the eye, and reflected sunlight from bright or shiny surfaces is equally disturbing and even disabling. A tightly woven white fabric with high solar transmittance attains such brilliance when illuminated by direct sunshine that, by contrast with its surroundings, it creates excessive glare. Off-white colors should be used so their surface brightness is not too great. Venetian blinds permit considerable light to enter by inter-reflection between slats. When two shading devices are used, the one on the inside (away from the window) should be darker and more open. With this arrangement, the inside can be used to control brightness for the other shading devices and, when used alone, reduce brightness while still permitting some view of the outside.

Table 33 Summary of Environmental Control Capabilities of Draperies

Item	Designator (Table 32 and Figure 31)								
	I_D	I_M	I_L	II_D	II_M	II_L	III_D	III_M	III_L
1. Protection from direct solar radiation and long-wave radiation to or from window areas	Fair	Fair	Fair	Fair	Good	Good	Fair	Good	Good
2. Effectiveness in allowing outward vision through fenestration	Good	Good	Fair	Fair	Fair	Some	None	None	None
3. Effectiveness in attaining privacy (limiting inward vision from outside)	None	None	Poor[a] Good[a]	Poor	Fair	Fair[a] Good[a]	Good[b]	Good[b]	Good[b]
4. Protection against excessive brightness and glare from sunshine and external objects	Mild	Mild	Mild[c] Poor[c]	Good	Good	Good[c] Poor[c]	Good	Good	Good[c] Poor[c]
5. Effectiveness in modifying unattractive or distracting view out of window	Little	Little	Some	Some	Good	Good	Blocks	Blocks	Blocks

[a]Good when bright illumination is on the viewing side.
[b]To obscure view completely, material must be completely opaque.
[c]Poor rating applies to white fabric in direct sunlight. Use off-white color to avoid excessive transmitted light.

View modification. When the view is unattractive or distracting, draperies modify the view to some degree, depending on the fabric weave and color (summarized in Table 33). Thus, the window remains an effective connection to the outside.

Sound control. Indoor shading devices, particularly draperies, can absorb some of the sounds originating within the room, but have little or no effect in preventing outdoor sounds from entering. For excessive internally generated sound, the usual remedy is to apply acoustical treatment to the ceiling and other room surfaces. While these materials can be effective in controlling sound, they are often located on the two horizontal surfaces (ceiling and floor) and leave the opposing vertical surfaces of glass and bare wall to reflect sound. The noise reduction coefficient (NRC = average absorptance coefficient at four frequencies) for venetian blinds is about 0.10, as compared to 0.02 for glass and 0.03 for plaster. For drapery fabrics at 100% fullness, NRC ranges from 0.10 to 0.65, depending on the tightness of weave. Class III (tightly woven) fabrics have NRC values of 0.35 to 0.65. Figure 32 shows the relation between NRC and openness factor for fabrics of normal weight.

Example 15. To select a drapery fabric, consider the five environmental factors listed in Table 31. Choose a fabric designator which has suitable performance for all the factors important to the case being considered. If this is not possible, make compromises resulting in an acceptable designator. Determine from Table 32 if the SC for the chosen designator is satisfactory. Specific cases follow:

1. Where modification of a distracting view is necessary, but a degree of outward vision is needed and an SC of 0.50 with 0.25-in. gray glass is satisfactory (see Table 33, Item 5), select II_M or II_L; Item 2, select II_M. The SC for II_M on Table 33 is approximately 0.46, therefore satisfactory.
2. Where protection from radiation is paramount and minimum SC is necessary (see Table 33, Item 1), select a closed weave, III_M or III_L. Since the SC for III_L is lowest (see Figure 32), choose III_L.
3. When good outward vision is desired, together with some reduction in brightness, choose I_M or I_D (Table 33).

Double Drapery

Double draperies (two sets of draperies covering the same area) have a light, open weave on the window side of the fenestration for outward vision and daylight when desired, and a heavy, close weave or opaque drapery on the room side to block out sunlight and provide privacy when desired. When properly selected and used, double draperies provide a reduced U-factor and a lowered SC.

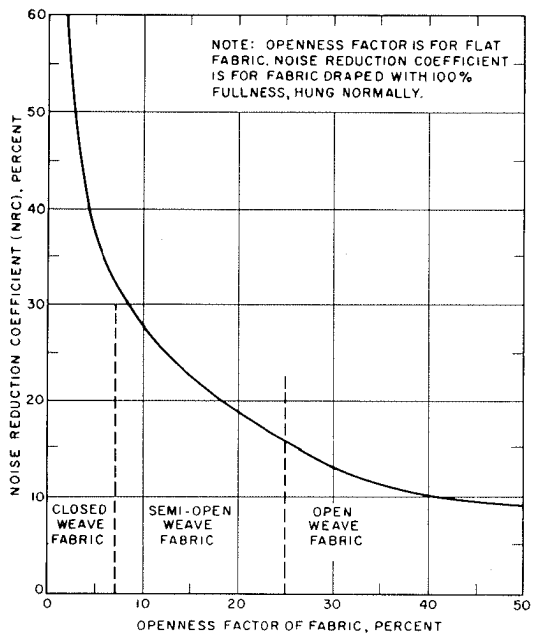

Fig. 32 Noise Reduction Coefficient versus Openess Factor

The reduced U-factor results principally from adding a semi-closed air space to the barrier. A U-factor of about 0.57 Btu/h·ft²·°F is achieved using double draperies with single glass, and about 0.37 Btu/h·ft²·°F with insulating glass.

To most effectively reduce solar heat gain, the drapery exposed to sunlight should have high reflectance and low transmittance. The light, open-weave drapery should be opened when the heavy drapery is closed to prevent entry of sunlight. The open weave drapery works better on the room side, since this arrangement improves the SC and increases the U-factor when both draperies are closed.

Properly used double draperies give (1) extreme flexibility of vision and light intensity, (2) a lowered U-factor and SC, and (3) an improved comfort condition, since the room-side drapery is more nearly at room temperature. Table 33 gives characteristics of individual draperies. For large areas, the SC should be calculated in detail to determine the cooling load.

Passive/Hybrid Cooling Systems 28.28
SIMULATION METHODS 28.33

THE energy requirements and fuel consumption of HVAC systems have a direct impact on the cost of operating a building and an indirect impact on the environment. This chapter discusses methods for estimating energy use as a guide in design, for standards compliance, and for economic optimization. The general requirements of an energy analysis are reviewed; then the various analysis methods are considered in order of increasing complexity—degree-day methods, bin methods, correlation methods, and transient simulation. The chapter concludes with a discussion of factors unique to solar energy systems.

These energy estimating methods can provide quantitative energy and cost comparisons among design alternatives. A large number of uncontrolled and unknown factors generally preclude, except in cases where extraordinarily detailed and careful measurements and observations have been made, the use of such methods for the precise calculation of absolute energy consumption. Thus, a careful measurement of energy use is the standard against which energy calculation results should be referenced. In no case should these methods be used to predict future utility bills.

GENERAL CONSIDERATIONS

PURPOSES

A primary objective of building energy analysis is economic—to determine which of the available options has the lowest total cost. Chapter 33 of the 1991 ASHRAE *Handbook—Applications* outlines how different analysis techniques can be used to optimize system selection and provides tables and data to assist in these analyses. Software programs are available to perform these calculations.

Many areas of engineering use life-cycle cost (LCC) optimization techniques in design. Unfortunately, LCC optimization has been inhibited by the complexity of buildings, which makes an analysis complex and costly, and by the uniqueness of each building, which makes it difficult to spread the cost of the analysis over several units. These barriers are being overcome, largely due to the availability of computer programs and inexpensive computers.

Many factors related to building energy system design are not considered in the LCC of a building. One example is the thermal comfort of the occupants, which affects productivity that could be accounted for if the relationship between the two were accurately known. A small loss in productivity due to reduced comfort can quickly offset an energy cost savings. Therefore, the designer must treat comfort conditions as constraints on a design rather than as variables to be included in the optimization.

Environmental impacts and other societal concerns also depend on building energy system design. However, they are difficult to quantify in an LCC optimization unless some authority provides a constraint or price signal. If the cost of equipment and energy that the designer plans to use reflects the total cost to society of producing them, then the optimum building design will be an optimum for society as well as for the building owner. If these costs fail to account for some societal costs, they are not considered, and the optimum design chosen for the building owner may not be an optimum for society.

A few building energy codes and standards allow the use of an energy analysis to demonstrate compliance with the energy performance goals in the code. This use of energy analysis programs may be more prevalent than actual comparative energy studies.

COMMON FACTORS

Although the procedures for estimating energy requirements vary considerably in their degree of complexity, they all have three common elements, *i.e.*, the calculation of (1) space load, (2) secondary equipment load, and (3) primary equipment energy requirements. Here, secondary refers to equipment that distributes the heating, cooling, or ventilating medium to conditioned spaces, while primary refers to central plant equipment that converts fuel or electric energy to heating or cooling effect. A major distinction is made between steady-state methods (based on degree days or temperature bins) and dynamic methods (*e.g.*, based on transfer functions).

The space load calculations determine the amounts of energy that must be added to or extracted from a space to maintain thermal comfort. The simplest procedures assume that the energy required to maintain comfort is only a function of the outdoor dry-bulb temperature. More detailed methods consider solar effects, internal gains, heat storage in the walls and interiors, and the effects of wind on both building envelope heat transfer and infiltration. These calculations are similar to the heating and cooling load calculations used to size equipment, but they are not the same. Energy calculations are based on average usage schedules and typical weather conditions rather than maximum usage schedules and worst case weather. The most sophisticated procedures are currently based on hourly profiles for climatic conditions

The preparation of this chapter is assigned to TC 4.7, Energy Calculations.

and operational characteristics for a number of typical days of the year or on 8760 h of operation per year.

The second step translates the space load into a load on the secondary system equipment. This can be a simple estimate of duct or piping losses or gains, or a complex hour-by-hour simulation of an air system, such as variable air volume with outdoor air cooling. This step must include the calculation of all forms of energy required by the secondary system, *i.e.*, electrical energy to operate fans and/or pumps, as well as energy in the form of heated or chilled water.

The third step calculates the fuel and energy required by the primary equipment to meet these loads and peak demand on the utility system. It considers equipment efficiencies and part-load characteristics. It is often necessary to keep track of the different forms of energy, such as electrical, natural gas, or oil. In some cases, where calculations are required to assure compliance with codes or standards, these energies must be converted to source energy or resource consumed, as opposed to energy delivered to the building boundary.

Often energy calculations lead to an economic analysis to establish the cost-effectiveness of conservation measures (ASHRAE 1989). Thus, thorough energy analysis provides intermediate data, such as time of energy usage and maximum demand, so that utility charges can be accurately estimated. Although not part of the energy calculations, estimated capital equipment costs should be included in such an analysis.

Complex and often unexpected interactions can occur between the systems or between various modes of heat transfer. For example, radiant heating panels impact the space loads by raising the mean radiant temperature in the space (Howell 1990). As a result, the air temperature can be lowered while maintaining comfort. Compared to a conventional heated air system, radiant panels create a greater temperature difference from the inside surface to the outside air. Thus, conduction losses through the walls and roof increase because the inside surface temperatures are greater. At the same time, the heating load due to infiltration or ventilation decreases because of the reduced indoor air to outdoor air temperature difference and a reduced stack effect. The infiltration rate may also decrease because the reduced air temperature difference reduces the stack effect.

CHOOSING AN ANALYSIS METHOD

The most important step in selecting an energy analysis method is to match the method capabilities with project requirements. The method must be capable of evaluating all design options with sufficient accuracy to make correct choices. The following factors apply generally (Sonderegger 1985):

- **Accuracy.** The method should be sufficiently accurate to allow correct choices. Because of the many parameters involved in energy estimation, absolutely accurate energy prediction is not possible (Waltz 1992).
- **Sensitivity.** The method should be sensitive to the design options being considered. The difference in energy use between two choices should be accurate.
- **Versatility.** The method should allow the analysis of all options under consideration. When different methods must be used to consider different options, an accurate estimate of the differential energy use cannot be made.
- **Speed and cost.** The total time (gathering data, preparing input, calculations, and analysis of output) to make an analysis should be appropriate to the potential benefits gained. With greater speed, more options can be considered in a given time. The cost of analysis is largely determined by the total time of analysis.
- **Reproducibility.** The method should not allow so many vaguely defined choices that different analysts would get completely different results (Corson 1992).
- **Ease of use.** This impacts both on the economics of analysis (speed) and the reproducibility of results.

Since almost all manual methods have been implemented on a computer, the selection of an energy analysis method is the selection of a computer program. The ASHRAE Journal's 1990 HVAC&R Software directory lists suppliers of various programs.

Selecting Energy Analysis Computer Programs

The selection of a building energy analysis program depends on its application, the number of times it will be used, the experience of the user, and the hardware available to run it. The first of the criteria to be considered must be the capability of the program to deal with the application. For example, if the effect of a shading device is to be analyzed on a building that will also be shaded by other buildings part of the time, the capability of analyzing detached shading is an absolute requirement, regardless of any other factors.

Today, all well-known programs run on microcomputers. Some programs require very large memory and hard disk capacities or need a very fast computer. However, the cost of the computer facilities and the software itself are typically a small part of carrying out a building energy analysis. The major costs are the cost of the effort involved in learning to use the program and the cost of the effort involved in using it. Major issues that influence the cost of learning a program include: (1) complexity of the input procedures, (2) quality of the user's manual, and (3) availability of a good support system to answer questions. As the user becomes more experienced, the cost of learning the program becomes less important. However, the requirement for a complex set of input data, will continue to consume the time of even an experienced user.

The complexity of input is largely influenced by the availability of default values for the input variables. Default values can be used as a simple set of input data when detail is not needed or when the building design is very conventional; but additional complexity can be supplied when needed. Secondary defaults, which can be supplied by the user, are also useful in the same way. Some programs allow the user to specify a level of detail. Then the program requests only the information appropriate to that level of detail, using default values for all others.

The quality of the output is another factor to consider. Reports should be easy to read and uncluttered. The titles and headings should be unambiguous. Units should be stated explicitly. The users' manual should explain the meanings of the data presented. Graphic output can be very helpful. In most cases, simple summaries of overall results are the most useful, but very detailed output is needed for certain studies and also for debugging program input during the early stages of an energy analysis project.

Before making a final decision, the user should obtain and review the users' manuals for the most suitable programs and, if possible, should obtain and run demonstration versions of the programs. During this last part of the selection process, the user should test the support from the software supplier. The availability of training should be considered when choosing a more complex program.

The availability of weather data and/or the availability of a weather data processing subroutine or program is a major feature of a program. Some programs include subroutine or supplementary programs that allow the user to create a weather file for any site for which weather data is available. Programs that do not have this capability must have weather files for various sites created by the program supplier. In that case, the available weather data and the terms on which the supplier will create new weather data files must be checked.

Auxiliary capabilities, such as economic analysis and design calculations, are a final concern in selecting a program. Economic

analysis may include only the ability to calculate annual energy bills from utility rates, or it might extend to calculations, or even to LCC optimization. An integrated program may save time, because some input data will have been entered already for other purposes.

The results of computer calculations should be accepted with caution as the software vendor does not accept responsibility for the correctness of calculations or the use of the program. A manual calculation should be run to develop a good understanding of the underlying physical processes and building behavior. In addition, the user should (1) review the computer program documentation to determine what calculation procedures are used, (2) compare the results with manual calculations and measured data, and (3) conduct sample tests to confirm that the program delivers acceptable results.

Since energy analysis computer programs take different approaches in their method of calculation, significant differences in results are found (Spielvogel 1977, Corson 1992).

STEADY-STATE METHODS

Degree-day methods are the simplest methods for energy analysis and are appropriate if the building use and the efficiency of the HVAC equipment are constant. Where efficiency or conditions of use vary with outdoor temperature, the consumption can be calculated for different values of the outdoor temperature and multiplied by the corresponding number of hours; this approach is used in various bin methods. When the indoor temperature is allowed to fluctuate or when interior gains vary, models other than simple steady-state models must be used.

Even in an age when computers can easily calculate the energy consumption of a building, the concepts of degree days and balance point temperature remain valuable tools. The severity of a climate can be characterized concisely in terms of degree days. Also, the degree-day method and its generalizations can provide a simple estimate of annual loads, which can be accurate if the indoor temperature and internal gains are relatively constant and if the heating or cooling systems are to operate for a complete season. For these reasons, basic steady-state methods continue to be important.

BALANCE POINT TEMPERATURE AND DEGREE DAYS

The balance point temperature t_{bal} of a building is defined as that value of the outdoor temperature t_o at which, for the specified value of the interior temperature t_i, the total heat loss q_{gain} is equal to the heat gain from sun, occupants, lights, and so forth.

$$q_{gain} = K_{tot}\,(t_i - t_{bal}) \tag{1}$$

where K_{tot} is the total heat loss coefficient of the building in Btu/h · °F. For any of the steady-state methods described in this section, heat gains must be the average for the period in question, not for the peak values. In particular, solar radiation must be based on averages, not peak values. The balance point temperature is therefore obtained as

$$t_{bal} = t_i - \frac{q_{gain}}{K_{tot}} \tag{2}$$

Heating is needed only when t_o drops below t_{bal}. The rate of energy consumption of the heating system is

$$q_h = \frac{K_{tot}}{\eta_h}\,[t_{bal} - t_o\,(\tau)]^+ \tag{3}$$

where η_h is the efficiency of the heating system, also designated on an annual basis as the annual fuel use efficiency (AFUE) and τ is time. If t_{bal}, K_{tot}, and η_h are constant, the annual heating consumption can be written as an integral

$$Q_{h,\,yr} = \frac{K_{tot}}{\eta_h}\int [t_{bal} - t_o\,(\tau)]^+\,d\tau \tag{4}$$

where the plus sign above the bracket indicates that only positive values are to be counted. This integral of the temperature difference conveniently summarizes the effect of outdoor temperatures on a building. In practice, it is approximated by summing averages over short time intervals (daily or hourly); the result is termed *degree days* or *degree hours*.

If daily average values of outdoor temperature are used for evaluating the integral, the degree days for heating $DD_h(t_{bal})$ are obtained as

$$DD_h\,(t_{bal}) = (1\text{ day}) \sum_{\text{days}} (t_{bal} - t_o)^+ \tag{5}$$

with dimensions of °F · days. Here the summation is to extend over the entire year or over the heating season. It is a function of t_{bal}, reflecting the roles of t_i, heat gain, and loss coefficient. The balance point temperature t_{bal} is also known as the base of the degree days. In terms of degree days, the annual heating consumption is

$$Q_{h,\,yr} = \frac{K_{tot}}{\eta_h}\,DD_h\,(t_{bal}) \tag{6}$$

Heating degree days or degree hours for a balance point temperature of 65 °F have been widely tabulated based on the observation that this has represented average conditions in typical buildings in the past. The 65 °F base is assumed whenever t_{bal} is not indicated explicitly. The extension of degree-day data to different bases will be discussed later.

Cooling degree days can be calculated using an expression analogous to heating degree days

$$DD_c\,(t_{bal}) = (1\text{ day}) \sum_{\text{days}} (t_o - t_{bal})^+ \tag{7}$$

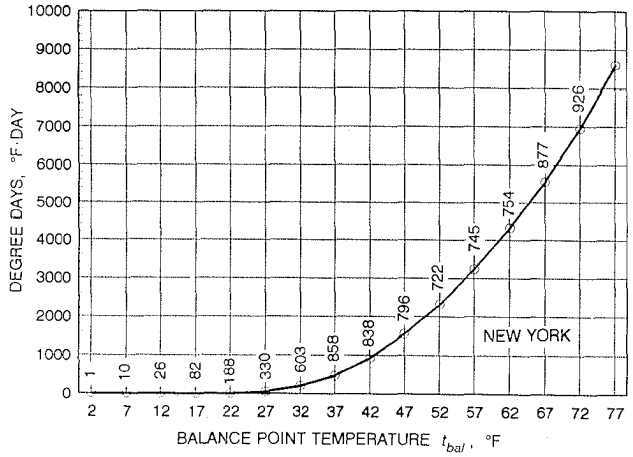
While the definition of the balance point temperature is the same as that for heating, in a given building its numerical value for cooling is generally different from that for heating because q_i, K_{tot}, and t_i can be different. According to Claridge *et al.* (1987), t_{bal} can include both solar and internal gains as well as losses to the ground.

In some cases, heating and cooling degree days for shorter time periods than a year are desirable, so that listings of monthly values are common.

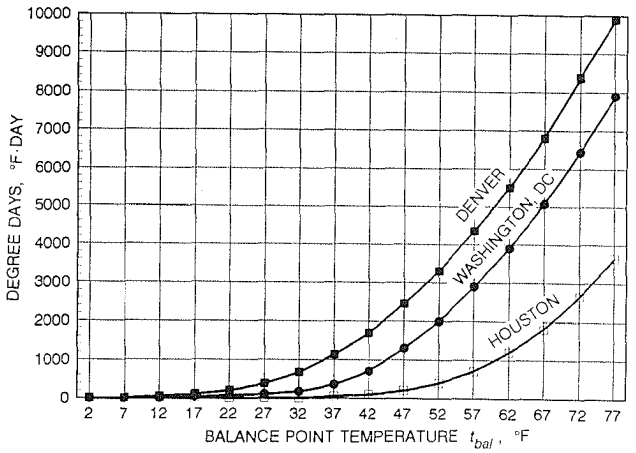
Figure 1(a) shows how the heating degree-days vary with t_{bal} for a particular site, *i.e.*, New York. This plot is obtained by evaluating Equation (5) with data for the number of hours per year during which t_o is within 5 °F temperature intervals centered at 72 °F, 67 °F, 62 °F, . . . , −8 °F. The data for the number of hours in each interval, or bin, are included as labels in this plot. Analogous curves, without these labels, are shown in Figure 1(b) for three other sites: Houston, Washington, and Denver.

If the annual average of t_o is known, the cooling degree days to any base below 72 + 2.5 °F can also be found. But calculating cooling energy consumption using degree days is more difficult than heating. For cooling, the equation analogous to Equation (6) is

$$Q_{c,\,yr} = \frac{K_{tot}}{\eta_c}\,DD_c\,(t_{bal}) \tag{8}$$



a. For New York, with labels = hours/year when t_o is in 5°F bin centered at the point (interpreting x-axis as t_o values)



b. For Denver, Houston, and Washington, D.C., degree days only.

Fig. 1 Annual Heating Days $DD_h(t_{bal})$ as Function of t_{bal}

for a building whose K_{tot} does not change. That assumption is generally acceptable during the heating season, when windows are closed and the air exchange rate is fairly constant. However, during the intermediate or cooling season, heat gains can be eliminated, and the onset of mechanical cooling can be postponed by opening windows or increasing the ventilation. (In buildings with mechanical ventilation, this is called the *economizer* mode.) Mechanical air conditioning is needed only when the outdoor temperature extends beyond the threshold t_{max}. This threshold is given by an equation analogous to Equation (2), with the replacement of the closed window heat transmission coefficient K_{tot} by its value K_{max} for open windows

$$t_{max} = t_i - \frac{q_{gain}}{K_{max}} \tag{9}$$

K_{max} varies considerably with wind speed; but for simple cases, assume a constant value. The resulting sensible cooling load is shown schematically in Figure 2 as a function of t_o. The solid line is the load with open windows or increased ventilation; the dashed line shows the load if K_{tot} were kept constant. The annual cooling load for this mode can be calculated by breaking the area under the solid line into a rectangle and a triangle, or

$$Q_c = K_{tot}\,[DD_c(t_{max}) + (t_{max} - t_{bal})\,N_{max}] \tag{10}$$

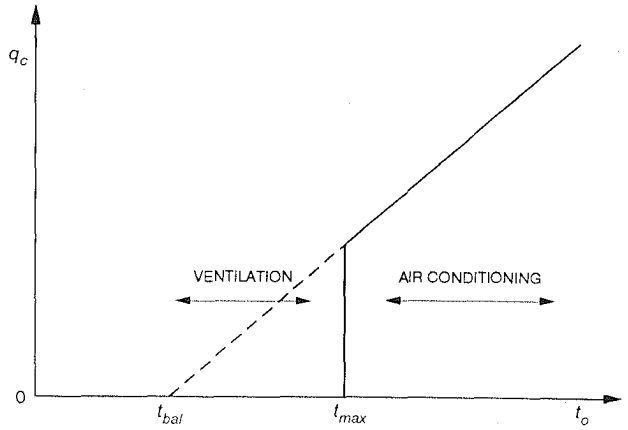


Fig. 2 Cooling Load as Function of Outdoor Temperature t_o (Below t_{max}, cooling can be avoided by using ventilation.)

where $DD_c(t_{max})$ are the cooling degree days for base t_{max}, and N_{max} is the number of days during the season when t_o rises above t_{max}. This is merely a schematic model of air conditioning. In practice, heat gains and ventilation rates vary, as does the occupant behavior in using the windows and the air conditioner. Also, in commercial buildings with economizers, the extra fan energy for increased ventilation must be added to the calculations. Finally, air-conditioning systems are often turned off during unoccupied periods. Therefore, cooling degree hours better represents the period when equipment is operating than cooling degree days, because degree days assume uninterrupted equipment operation as long as there is a cooling load.

Latent loads can form an appreciable part of a building's cooling load. The degree-day method can be used to estimate the latent load during the cooling season on a monthly basis by adding the following term to Equation (10):

$$Q_{latent} = \dot{m} h_{fg} (W_o - W_i) \tag{11}$$

where

q_{latent} = monthly latent cooling load
$\dot{m}$ = monthly infiltration (total airflow)
h_{fg} = heat of vaporization of water
W_o = outdoor humidity ratio (monthly averaged)
W_i = indoor humidity ratio (monthly averaged)

The degree-day method assumes that t_{bal} is constant, which is not well satisfied in practice. Solar gains are zero at night, and internal gains tend to be highest during the evening. The pattern for a typical house is shown in Figure 3. As long as t_o always stays below t_{bal}, the variations average out without changing the consumption. But for the situation in Figure 3, t_o rises above t_{bal} from shortly after 10:00 A.M. to 10:00 P.M.; the consequences for energy consumption depend on the thermal inertia and on the control of the HVAC system. If this building had low inertia, and if temperature control were critical, heating would be needed at night and cooling during the day. In practice, this effect is reduced by thermal inertia and by the deadband of the thermostat which allows t_i to float.

The closer t_o is to t_{bal}, the greater the uncertainty. If the occupants keep the windows closed during mild weather, t_i will rise above the set point. If they open the windows, the potential benefit of heat gains is reduced. In either case, the true values of t_{bal} become uncertain. Therefore, the degree-day method, like any

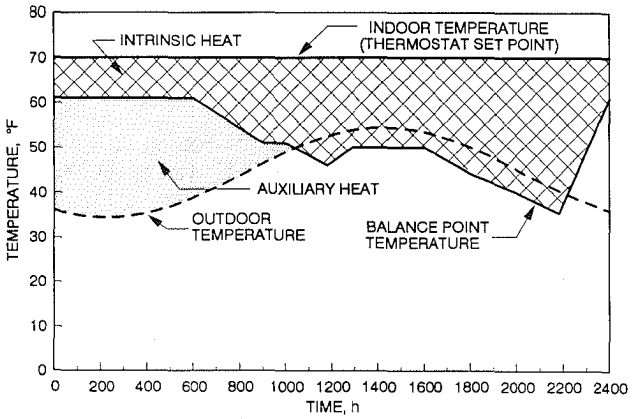

Fig. 3 Variation of Balance Point Temperature and Internal Gains for Typical House
(Nisson and Dutt 1985)

steady-state method, is unreliable for estimating the consumption during mild weather. In fact, the consumption becomes most sensitive to occupant behavior and cannot be predicted with certainty.

Despite these problems, the degree-day method (using an appropriate base temperature) can give remarkably accurate results for the annual heating energy of single-zone buildings dominated by gains through the walls and roof and/or ventilation. Typical buildings have time constants that are about one day, and a building's thermal inertia essentially averages over the diurnal variations, especially if t_i is allowed to float. Furthermore, the energy consumption in mild weather is small; hence a relatively large error here has only a small effect on the total for the season.

Seasonal Efficiency

The seasonal efficiency of heating equipment η_h depends on such factors as steady-state efficiency, sizing, cycling effects, and energy conservation devices. Sometimes it is much lower than and other times it is comparable to steady-state efficiency. Alereza and Kusuda (1982) developed expressions to estimate the seasonal efficiency for a variety of furnaces, if information on rated input and output is available. These expressions correlate seasonal efficiency with variables determined by using the equipment simulation capabilities of a large hourly simulation program and typical equipment performance curves supplied by the National Institute of Standards and Technology.

$$\bar{\eta} = \eta_{ss}\, CF_{pl}/(1 + \alpha_D) \tag{12}$$

where

η_{ss} = steady-state efficiency (rated output/input)
α_D = fraction of heat loss from ducts

The term CF_{pl} is a characteristic of the part-load efficiency of the heating equipment, which may be calculated as follows:

Gas-forced air furnaces

With pilot

$$CF_{pl} = 0.6328 + 0.5738\,RLC - 0.3323\,(RLC)^2$$

With intermittent ignition

$$CF_{pl} = 0.7791 + 0.1983\,RLC - 0.0711\,(RLC)^2$$

With intermittent ignition and loose stack damper

$$CF_{pl} = 0.9276 + 0.0732\,RLC - 0.0284\,(RLC)^2$$

Oil furnaces without stack damper

$$CF_{pl} = 0.7092 + 0.6515\,RLC - 0.4711\,(RLC)^2$$

Resistance electric furnaces

$$CF_{pl} = 1.0$$

These equations are based on many annual simulations for the equipment in which RLC is defined as follows:

$$RLC = BLC\,(t_{bal} - t_{od})(1 + \alpha_D)/CHT$$

where

t_{od} = outside design temperature
CHT = rated output of equipment

Seasonal efficiency is also discussed by Chi and Kelly (1978), Parker *et al.* (1980), and Mitchell (1983).

VARIABLE BASE DEGREE DAYS

The calculation of Q_h from degree days DD_h (t_{bal}) depends on the value of t_{bal}. This value varies widely from one building to another because of widely differing personal preferences for thermostat settings and setbacks and because of different building characteristics. In response to the fuel crises of the 1970s, heat transmission coefficients have been reduced, and thermostat setback has become common. At the same time, the energy use by appliances has increased. These trends all reduce t_{bal} (Fels and Goldberg 1986). Hence, in general, degree days with the traditional base 65 °F are not to be used.

Many formulas have been proposed for estimating the degree days relative to an arbitrary base when detailed data are not available. The basic idea is to assume a typical probability distribution of temperature data, characterized by its average $\bar{t}_o$ and by its standard deviation σ. Erbs *et al.* (1983) developed a model that needs as input only the average $\bar{t}_o$ for each month of the year. The standard deviations σ_m for each month are then estimated from the correlation

$$\sigma_m = 3.54 - 0.0290\,\bar{t}_o + 0.0664\,\sigma_{yr} \tag{13a}$$

This is a dimensional equation with t and σ in °F; σ_{yr} is the standard deviation of the monthly average temperatures about the annual average $\bar{t}_{o,\,yr}$

$$\sigma_{yr} = \sqrt{\frac{1}{12}\sum_{1}^{12}(\bar{t}_o - \bar{t}_{o,\,yr})^2} \tag{13b}$$

To obtain a simple expression for the degree days, a normalized temperature variable θ is defined as

$$\theta = \frac{t_{bal} - \bar{t}_o}{\sigma_m\sqrt{N}} \tag{14}$$

with N = number of days in the month (N has units of day/month and θ has units of $\sqrt{\text{month/day}}$). While temperature distributions can be different from month to month and location to location, most of this variability can be accounted for by the average and the standard deviation of $\bar{t}_o$. Being centered around $\bar{t}_o$ and scaled by σ_m, the quantity θ eliminates these effects. In terms of θ,

the monthly heating degree days for any location are well approximated by

$$DD_h(t_{bal}) = \sigma_m N^{3/2}\left[\frac{\theta}{2} + \frac{\ln(e^{-a\theta} + e^{a\theta})}{2a}\right] \quad (15)$$

where $a = 1.698\sqrt{\text{day/mo.}}$

For nine locations spanning most climatic zones of the United States, Erbs *et al.* (1983) verified that the annual heating degree days can be estimated with a maximum error of 315 °F-days if this equation is used for each month. For cooling degree days, the largest error is 270 °F-days. Such errors are quite acceptable, representing less than 5% of the total.

Example 1. Find the monthly heating degree-days for New York City, using the model of Erbs *et al.* (1983), given monthly averages of t_o as reproduced in column 2 of Table 1. Base the degree days on a balance temperature of 60 °F.

The results are included in Table 1. Column 2 lists the given values of monthly average outdoor temperature, and N is the number of days in the month. Intermediate quantities are shown in columns 4 and 5, and $t_{o,yr}$ and σ_{yr} are shown at the bottom. Column 6 shows the monthly and annual results.

Table 2 contains degree-day data for several sites and monthly averaged outdoor temperatures needed for the algorithm used in the example. More complete tabulations of the latter are contained in Cinquemani *et al.* (1978) and in local climatological data summaries available from the National Climatic Data Center, Asheville, NC. Monthly degree-day data to the bases of 50 °F, 55 °F, 60 °F, 65 °F, and 70 °F, as well as other climatic information for 209 U.S. and 14 Canadian cities, may be found in Appendix 3 to Balcomb *et al.* (1982).

Table 1 Degree-Day Calculation from Monthly Averaged Data

Month	$\bar{t}_o$, °F	N, day/mo.	σ_m, °F	σ, $\sqrt{\text{mo./day}}$	$DD_h(t_{bal})$, °F · day
January	32.2	31	3.65	1.37	864

$t_{o,yr}$	54.4			Sum	3837
σ_{yr}	15.8				

Note: Use Equation (15) to calculate $DD_h(t_{bal})$

BIN METHOD

For many applications, the degree-day method should not be used, even with the variable base method, because the heat loss coefficient K_{tot}, the efficiency η_h of the HVAC system, or the balance point temperature may not be sufficiently constant. The efficiency of a heat pump, for example, varies strongly with outdoor temperature; or the efficiency of the HVAC equipment may be affected indirectly by t_o when the efficiency varies with the load, a common situation for boilers and chillers. Furthermore, in most commercial buildings, the occupancy has a pronounced pattern, which affects heat gain, indoor temperature, and ventilation rate.

In such cases, a steady-state calculation can yield good results for the annual energy consumption, if different temperature intervals and time periods are evaluated separately. This approach is known as the bin method, because the consumption is calculated for several values of the outdoor temperature t_o and multiplied by the number of hours N_{bin} in the temperature interval (bin) centered around that temperature

$$Q_{bin} = N_{bin}\frac{K_{tot}}{\eta_h}[t_{bal} - t_o]^+ \quad (16)$$

The superscript plus sign indicates that only positive values are counted; no heating is needed when t_o is above t_{bal}. This equation is evaluated for each bin, and the total consumption is the sum of the Q_{bin} over all bins.

In the United States, the necessary data are widely available (ASHRAE 1984, USAF 1978). The bins are usually in 5 °F increments and are often collected in three daily 8-h shifts. Mean coincident wet-bulb temperature data (for each dry-bulb bin) are used to calculate latent cooling loads from infiltration and ventilation. The bin method considers both occupied and unoccupied building conditions and gives credit for internal loads by adjusting the balance point. For example, a calculation could be performed for 42 °F outdoors (representing all occurrences from 39.5 to 44.5 °F) and with building operation during the midnight to 0800 shift. Since there are 23 5 °F bins between −10 and 105 °F and 3 8-h shifts, 69 separate operating points are calculated. For many applications, the number of calculations can be reduced. A residential heat pump (heating mode), for example, could be calculated for just the bins below 65 °F without the three-shift breakdown. The data included in Table 3 are samples of annual totals for a few sites, but ASHRAE (1984) and USAF (1978) include monthly data and data further separated into time intervals during the day.

[b]Source: Cinquemani *et al.* (1978)

Example 2. Estimate the energy requirements for a residence in Washington, D.C., with a design heat loss of 40,000 Btu/h at 53°F temperature difference. Assume a 3-ton heat pump, with characteristics given in Figure 4 and Table 4.

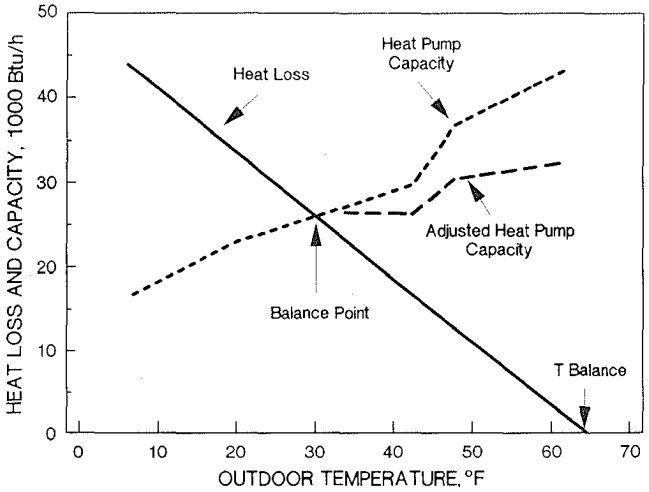

Fig. 4 Heat Pump Capacity versus Building Load

Solution: The design heat loss is based on no internal heat generation. To compute the heat pump system energy input, compute the net heat requirement of the space, *i.e.*, envelope loss minus internal heat generation. For this example, assume an average internal heat generation of 4280 Btu/h and a room temperature of 70°F. The net heat loss per degree and the heating/cooling balance temperature may be computed:

$$(HL/\Delta t) = (40{,}000/53) = 755 \text{ Btu/h}\cdot°F$$

$$t_{balance} = 70 - (4280/755) = 64.3°F$$

Table 4 is then computed resulting in 9578 kWh.

Figure 4 shows the relationship between heat loss and the integrated heat pump capacity. The balance point occurs at the temperature where the heat loss and steady-state capacity are equal. At lower temperatures, supplemental heat is required, and at higher temperatures the heat pump cycles on and off.

To properly predict the energy use of the heat pump system, actual dynamic performance data, including cycling losses, should be used. For the heat pump system, performance data should include the effects of cycling above the building balance temperature, frosting, defrosting, and the effect of auxiliaries. These losses may be significant, depending on the size of the heat pump compared to the building heat loss and the control methodology of the heat pump.

[a]Cycling Capacity Adjustment Factor = $1 - C_d(1 - x)$ when C_d = degradation coefficient, default = 0.25, unless part load factor is known, and x = building heat loss/unit capacity at temperature bin. Cycling capacity = 1 at the balance point and below.
[b]Col. G = Col. E × Col. F
[c]Operating Time Factor equals the smaller of 1 or Col. D/Col. G
[d]Col. J = (Col. I × Col. G × Col. C)/1000
[e]Col. K = Col. I × Col. H × Col. C
[f]Col. L = Col. C × Col. D/1000
[g]Col. M = Col. L − Col. J
[h]Col. N = Col. K + Col. M

The Department of Energy has adopted test procedures (10 CFR 430, Appendix M, USGPO) to determine the effect of dynamic operations. The bin method uses these results for a specific heat pump to adjust the integrated capacity for the effect of part-load operation. Figure 4 compares the adjusted heat pump capacity to the building heat loss. This type of curve must be developed for each model heat pump as applied to an individual profile. The heat pump cycles on and off above the balance point temperature to meet the house load. This cycling can reduce performance depending on the part-load factor at a given temperature. The cycling capacity adjustment factors (ANSI/ASHRAE *Standard* 116-1983) used in this example to account for cycling degradation can be calculated from the equation in footnote a of Table 4.

Frosting and the necessary defrost cycle can reduce performance over steady-state conditions that do not include frosting. The effects of frosting and defrosting are already integrated into many (but not all) manufacturers' performance data. The example problem assumes that the manufacturers' data already accounts for the frosting/defrosting losses (as indicated by the characteristic notch of the capacity curve in Figure 4) and shows how to adjust an integrated performance curve for cycling losses. For those cases where the manufacturers' data on heating capacities do not include the effect of defrost cycles in the temperature range where they occur, steady-state, instant system capacities at a given outdoor temperature should be multiplied by a factor X_{int} to obtain the integrated heating capacity to be used in the annual energy calculation. The factor X_{int} is given by

$$\begin{aligned} X_{int} &= 1.0 \text{ for } t_o \geq 45\,^\circ\text{F} \\ &= 1.0 - (0.02)(45 - t_o) \text{ for } 40\,^\circ\text{F} \leq t_o < 45\,^\circ\text{F} \\ &= 0.95 - 0.00125\, t_o \text{ for } t_o < 40\,^\circ\text{F} \end{aligned}$$

where t_o is the outdoor dry-bulb temperature (Didion and Kelly 1979).

The total annual heating energy consumption used by the heat pump in this example is computed in Table 4 using bin weather data. Column F contains the capacity adjustment factor used to account for losses due to cycling.

Degree-Day Data from Bin Data

To calculate degree days from hourly bin data such as those in ASHRAE (1984), the base or balance temperature t_{bal} must first be determined. When t_{bal} is known, the following summation can be used on any time scale, either monthly or annually, or for several periods of a day on either a monthly or annual basis.

$$DD_h(t_{bal}) = \frac{1}{24}\left(\sum_{bins} (t_{bal} - t_{bin})^+ N_{bin}\right) \quad (17)$$

where

t_{bin} = temperature at center of bin
N_{bin} = number of hours in bin corresponding to t_{bin}

Cooling degree days are calculated analogously from

$$DD_c(t_{bal}) = \frac{1}{24}\left(\sum_{bins} (t_{bin} - t_{bal})^+ N_{bin}\right) \quad (18)$$

This method generally produces degree-day values slightly higher than published values from NOAA or the NCDC. This small but systematic deviation can be suppressed by ignoring degree days during the swing seasons when totals are less than a minimum, *e.g.*, 50 to 100 °F-days per month. During such periods, thermal storage of daytime heat often makes nighttime heating unnecessary.

Modified Bin Method

Various refinements, such as the seasonal variation of solar gains, can be included in a bin calculation. If a separate calculation is done for each month, Q_{gain} could be based on the average solar heat gain of the month. The diurnal variation of solar gains can be accounted for by calculating the average solar gain for each of the hourly time periods of the bin method. If such a detailed calculation of solar gains is considered unnecessary, assume a linear correlation of monthly average solar heat gains with monthly average outdoor temperature t_o.

This procedure is illustrated in Figure 5(a) for the simplest case—a building with constant operating conditions every hour of the day and every day of the year (*i.e.*, t_i, K_{tot}, and nonsolar heat gains $q_{non\text{-}sol}$ are all constant). In this case, it suffices to calculate the daily average heating load q_{heat} for the peak winter day and the daily average cooling load q_{cool} on the peak summer day

$$q_{heat} = K_{tot}(t_i - t_{peak,\,winter}) - q_{non\text{-}sol} - q_{sol,\,winter} \quad (19)$$

and

$$q_{cool} = K_{tot}(t_i - t_{peak,\,summer}) - q_{non\text{-}sol} - q_{sol,\,summer} \quad (20)$$

where $t_{peak,\,winter}$ and $t_{peak,\,summer}$ are the design winter and summer outdoor temperatures and $q_{sol,\,winter}$ and $q_{sol,\,summer}$ are the corresponding daily average solar gains. The solar gains in Equations (19) and (20) are totals for all orientations of windows, roofs, and walls. Solar gains are calculated for each building element for summer and winter days and then summed to form the building total for the summer and winter endpoints of the load line in Figure 5 [see Knebel (1983) for details]. In the northern hemisphere, the summer month is usually taken as July and the winter month as January.

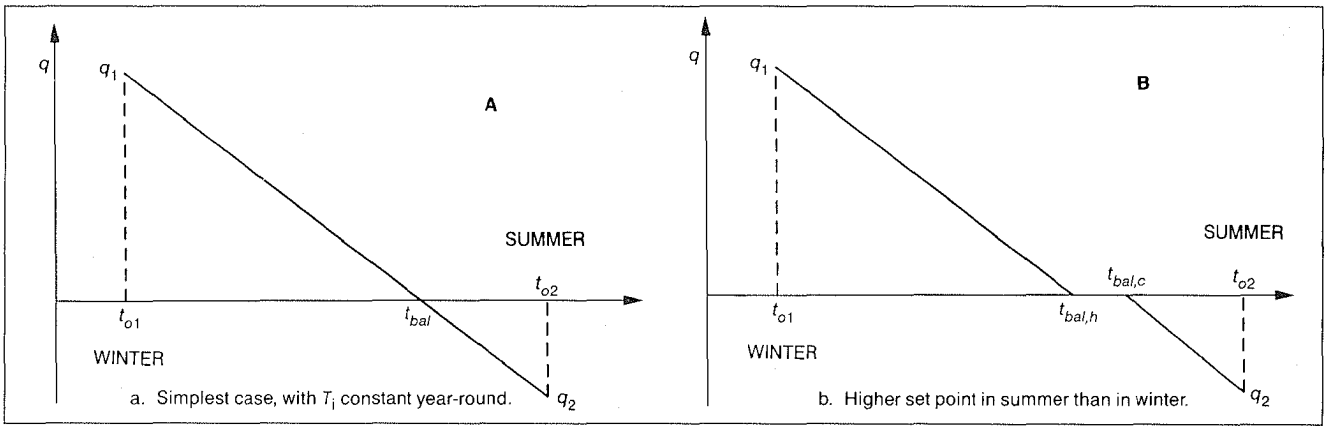

Fig. 5 Load as Function of Outdoor Temperature T_o (Ventilative cooling not shown.)

In equation form, the solar flux ordinate for fenestration in Figure 5 is found from

$$q_{sol,\,summer} = \frac{\sum_{i=1}^{N_{exp}} \mathrm{MSHGF}_i \cdot \mathrm{AG}_i \cdot \mathrm{SC}_i \cdot \mathrm{CLFTOT}_i \cdot \mathrm{FPS}}{\theta A_f} \quad (21)$$

where

N_{exp} = number of building surfaces (exposures)
MSHGF_i = maximum solar heat gain factor for exposure i
AG_i = glazing area for exposure i
SC_i = shading coefficient of exposure i
CLFTOT_i = daily total cooling load factor for exposure i
FPS = fraction of possible sunshine for summer design month
A_f = floor area [the modified bin method algorithm of Knebel (1983) is executed on a per unit floor area basis]
θ = operating time (h/day) of HVAC system in summer

Note: The methodology for calculating the daily-average hourly solar heat gain is taken from the section Air-Conditioning Cooling Load in Chapter 26 of the 1989 ASHRAE *Handbook—Fundamentals*; the maximum solar gain factors and cooling load factors used in this and related calculations can be obtained from that source. However, the methodology has been significantly improved; for the revised procedure, consult McQuiston and Spitler (1992).

The solar component of the winter load line endpoint is found from a similar equation, except that the corresponding winter values for all terms are used. Also, the value of θ is 24 h for the winter endpoint.

The total summer and winter load values are plotted versus the corresponding outdoor temperatures. Connecting these two points by a straight line, a simple linear approximation for the load as a function of outdoor temperature t_o is obtained. The balance point temperature t_{bal} of Equation (2) is the value of t_o where this line crosses the abscissa.

This approach does not estimate solar-related loads well for all climates (Vadon *et al.* 1991), since the endpoints of the solar load lines are defined by the infrequently occurring maximum and minimum bin temperatures. Improvements are possible if solar gains are related to a different outdoor dry-bulb temperature statistic, the annual standard deviation σ_t of hourly data about the annual mean.

The solar flux on any vertical surface of a building is given by the following set of equations. The solar flux is linear with bin temperature (Figure 5), but the slope and intercept are not determined by peak design conditions. The solar flux I in any bin is

$$I = mt_{bin} + b \quad (22)$$

The slope m and intercept b of this linear expression are given by

$$m = \frac{A}{\sqrt{\sigma_t}} + B \quad (23)$$

$$b = \frac{C}{\sqrt{\sigma_t}} + D \quad (24)$$

The standard deviation of hourly temperature is found from

$$\sigma_t = \sqrt{\frac{1}{8759} \sum_{i=1}^{N} N_{bin,\,i} (t_i - \bar{t}_{o,\,yr})^2} \quad (25)$$

where N is the number of bins.

The coefficients in this equation depend on the surface azimuth angle

$$\begin{aligned} A &= 10.63 - 4.980 \cos (a_w - 1) \\ B &= -1.887 - 0.9754 \cos (a_w - 0.5) \\ C &= -837.73 - 398.39 \cos (a_w - 1) \\ D &= 223.29 + 100.53 \cos (a_w - 0.5) \end{aligned} \quad (26)$$

in which the wall azimuth a_w is expressed in radians, with south zero and west positive. Note that the preceding equations are dimensional, with solar flux being in Btu/h·ft².

Equations (22) through (26) are used as follows. The modified bin method load line endpoints are dependent on the solar gain terms as described in the previous section. The term $\mathrm{MSHGF}_i \cdot \mathrm{FPS}$ is replaced by $0.87I$, I being found from Equation (22). The constant 0.87 accounts for the basis of SHGF being single-strength glass (see Chapter 26).

After dividing by the equipment efficiency (using the proper part-load value for each bin), the annual heating energy is found by summing over all temperature bins below the balance point, each bin weighted by the corresponding number of hours. The same can be done for cooling above the balance point temperature, although ventilative cooling should be taken into account according to Figure 2.

It is customary to set the thermostat a few degrees higher in summer than in winter. This has the effect of displacing the cooling characteristic line to the right as shown in Figure 5(b). Evaluating q_{cool} for the higher summer value of t_i, one finds by how much the cooling part of the line is shifted to the right.

As a further refinement, a separate calculation of the solar gain for the transition season, when t_o is close to the values of t_{bal}, could be performed. Then the corrected values of the points ($t_{bal,\,heat}$ and $t_{bal,\,cool}$) where the lines intersect the $q = o$ axis are calculated with the mid-season solar gain. Now the slopes for heating and for cooling can be different.

Finally, the correlations shown in Figure 5(b) can be developed separately for different times of the day and for different occupancy conditions, for example, 1200 to 1600 on Saturdays. Using bin data for the corresponding periods, the calculation can thus account for the operating schedules of commercial buildings.

The modified bin method has the advantage of allowing the use of diversified (part-load) rather than peak load values to establish the load as a function of outdoor dry-bulb temperature. This method also allows both secondary and primary (plant) HVAC equipment effects to be included in the energy calculation. The modified bin method permits the user to predict more accurately effects such as reheat and heat recovery that can only be guessed at with the degree-day or conventional bin methods.

In the modified bin method, average solar gain profiles, average equipment and lighting use profiles, and cooling load temperature difference (CLTD) values are used to characterize time-dependent diversified loads. An improved method is described in Claridge *et al.* (1992a, 1992b). The CLTDs approximate the transient effects of building mass. Time dependencies resulting from scheduling are averaged over a selected period, or multiple calculation periods are established. The duration of a calculation period determines the number of bin hours included. Normally, two calculation periods representing occupied and unoccupied hours are sufficient, although any number can be used. The method can be further refined by making calculations on a monthly, not annual, basis.

As described earlier, loads resulting from solar gains through glazings are calculated by determining a weighted-average solar load for a summer and for a winter day (each being of average

cloudiness and having average solar conditions), and then establishing a linear relationship of this solar load as a function of outdoor temperature. When outdoor ambient temperature exceeds room temperature, the effect of heat transfer through opaque, sunlit roofs and walls is included in the transmission load by averaging the CLTDs from Chapter 26 and applying corrections for deviations from the CLTD-reference outdoor-to-indoor temperature difference.

Once a total load profile is determined as a function of outdoor ambient temperature for occupied and unoccupied periods, the performance of the HVAC system is computed based on the heating and cooling coil loads. Next, the annual energy consumption at the coils is determined using bin-hour weather data. Finally, the annual plant energy consumption is calculated using boiler and chiller part-load performance models. Example 3 demonstrates the first step of this method (diversified coil loads) as applied to a variable air volume system; note that it could be applied to any type of system.

Example 3. Given the following information, determine the annual energy consumption for an office building with the simplified floor plan shown in Figure 6.

1. Building type: office, single-story
2. Location: Washington, D.C., near Andrews Air Force Base
3. Summer design load: 515,000 Btu/h
4. Summer outside design conditions: 90°F db, 74°F wb
   Fraction possible sunshine (FPS) = 0.64
5. Inside design conditions (occupied hours): 75°F db, 50% rh. This is chosen as constant throughout the year to simplify the example. Different set points can be used for the heating and cooling season. During unoccupied hours, a 55°F setback is used, and the cooling coils are shut off.
6. Winter design load: 285,200 Btu/h. These design loads were calculated using standard ASHRAE heating load methods (Chapter 25).
7. Winter outside design conditions: 14°F db (Chapter 24)
   FPS = 0.44
8. *Physical data*

   Gross floor area: 15,000 ft²
   Net conditioned area: 12,000 ft²
   Perimeter depth: 12 ft
   Interior space area: 6576 ft²
   Perimeter space area: 5424 ft²

   Surface data

Direction	Wall Area, ft²	Glass Area, ft²
N	900	900
E	600	600
S	900	900
W	600	600

Wall: U = 0.0684 Btu/h·ft²·°F (group G)
Glazing: UG = 0.97 Btu/h·ft·°F
Glazing: SC = 0.55
Roof: U = 0.0807 Btu/h·ft²·°F (type 3)

9. *Internal loads and schedules*

   Lights: 2.5 W/ft²
   0700 to 1900, Mon-Fri, except holidays
   0.25 W/ft² otherwise
   Utilization factor (UF) = 0.8 (constant)

   Equipment: 1.0 W/ft²
   0700 to 1900, Mon-Fri, except holidays
   0 W/ft² other times

   People: 1 person/100 ft²
   0700 to 1900, Mon-Fri, except holidays
   0 person/ft² otherwise
   Q_S = 255 Btu/h·person
   Q_L = 255 Btu/h·person

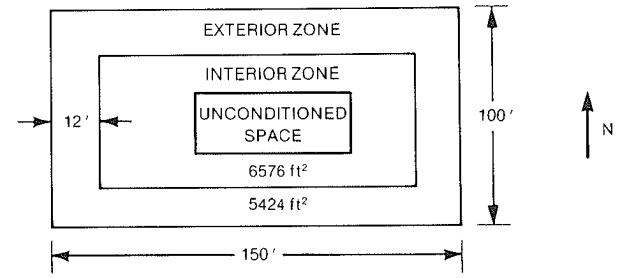

Fig. 6 Floor Plan of Building for Example 3

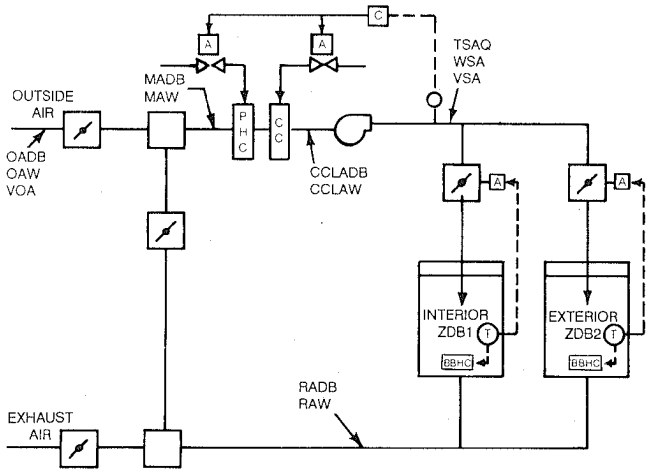

Fig. 7 Variable Air Volume System with Baseboard Heating (Example 3)

10. Ventilation: 0.2 cfm/ft²
    0.05 cfm/ft² (unoccupied period)
11. *Air distribution system data* (Figure 7)

    Variable air volume in both interior and exterior zones, with baseboard heat in perimeter space
    Design supply air temperature: 55°F
    (includes a 2°F drawthrough fan temperature rise)
    Design supply air: 20,000 cfm
    Design power: 17.3 hp

The design load was calculated using the CLTD/CLF cooling load method described in Chapter 26. A construction of 87 lb/ft² (medium weight) was assumed. CLFs for this construction weight, assuming interior shading (SC = 0.55), were used to calculate the solar gain through the glazings for July. CLTDs for Group G walls and a Type 3 roof (with suspended ceiling) were used to calculate heat gains through opaque envelope surfaces. Corrections were made for outside and inside temperature conditions. A corrected CLTD for conduction through glass was used. The internal heat gains listed in item 9 result in the design supply airflow rate and summer design load at the cooling coil.

Solution: Calculate the zone load, HVAC system coil loads, and primary equipment energy input at all outdoor air temperature bins.

1. *Sub-building or zone selection.* This building has four distinct perimeter zones and an interior zone. If the perimeter spaces are physically separated from the interior zone, each of the perimeter and the interior zones will exhibit a different load profile. In this case, the building should be subdivided into five separate zones for analysis—the four perimeter zones and the interior zone. However, to simplify this example, the building will be subdivided into two zones—one perimeter zone and one interior zone.

2. *Perimeter zone diversified loads.*

(a) Solar heat gain through glass—July

$$QSOL,Jul = \frac{\sum_{i=1}^{N_{exp}} (MSHGF_i \cdot AG_i \cdot SC_i \cdot CLFTOT_i \cdot FPS)}{\theta A_F}$$

where

QSOL,Jul = averaged solar contribution for July
$MSHGF_i$ = maximum solar heat gain factor for orientation i for July at specified latitude
AG_i = glass area for exposure i
SC_i = shading coefficient of glass for exposure i
$CLFTOT_i$ = 24-h sum of CLF for orientation i
FPS = fraction of possible sunshine for July
θ = runtime of air-conditioning system, h (12 h)
A_F = building conditioned floor area, ft²

Exposure	MSHGF ×	AG ×	SC ×	CLFTOT ×	FPS	= Numerator
N	38	900	0.55	11.57	0.64	139,284
E	216	600	0.55	5.46	0.64	249,080
S	109	900	0.55	6.43	0.64	222,035
W	216	600	0.55	5.46	0.64	249,080
					TOTAL =	859,479 Btu/day

QSOL,Jul = 859,479/(12 × 12,000) = 5.969 Btu/h · ft²

(b) Solar heat gain through glass—January

$$QSOL,Jan = \frac{\sum_{i=1}^{N_{exp}} (MSHGF_i \cdot AG_i \cdot SC_i \cdot CLFTOT_i \cdot FPS)}{24 A_F}$$

where

$MSHGF_i$ = maximum solar heat gain factor for orientation i for January at specified latitude
FPS = fraction of possible sunshine in January

Exposure	MSHGF ×	AG ×	SC ×	CLFTOT ×	PPS	= Numerator
N	20	900	0.55	11.57	0.44	50,399
E	154	600	0.55	5.46	0.44	122,090
S	254	900	0.55	6.43	0.44	355,715
W	154	600	0.55	5.46	0.44	122,090
					TOTAL =	650,294 Btu/day

QSOL,Jan = 650,294/(24 × 12,000) = 2.258 Btu/h · ft²

(c) Linearize solar contribution from glass with outside air temperature.

QSOL may be expressed as:

$$QSOL = M(t - t_{ph}) + QSOL,Jan$$

where

t = summer bin temperature
t_{ph} = winter peak bin temperature
t_{pc} = summer peak bin temperature (Table 8)

$$M = \frac{QSOL,Jul - QSOL,Jan}{t_{pc} - t_{ph}}$$

$$= \frac{5.969 - 2.258}{97 - 2} = 0.03906$$

$$QSOL = 0.03906(t - 2) + 2.258$$
$$= 0.03906\, t + 2.1799\ (Btu/h \cdot ft^2)$$

(d) Transmission solar loads

Compute solar component through opaque walls in July.

N	900	0.0684	0	1.0	0.44	= 0.00
E	600	0.0684	6	1.0	0.44	= 108.34
S	900	0.0684	21	1.0	0.44	= 568.81
W	600	0.0684	6	1.0	0.44	= 108.34
ROOF	5424	0.0807	3	1.0	0.44	= 577.80
					TOTAL =	1363.29 Btu/h

QTS, Jan = 1363.29/12,000 = 0.1136 Btu/h · ft²

Linearize solar contribution *from opaque walls* with outside air temperature:

QTS may be expressed as:

$$QTS = M(t - t_{ph}) + QTS,Jan$$
$$M = (QTS,Jul - QTS,Jan)/(t_{pc} - t_{ph})$$
$$= (0.6285 - 0.1136)/(97 - 2) = 0.00542$$
$$QTS = 0.00542(t - 2) + 0.1136$$
$$= 0.00542\, t + 0.1028\ (Btu/h \cdot ft^2)$$

Note: This contribution to the diversified load is much less than the solar contribution through glass. Where there are large expanses of glass, ignore this term.

(e) Transmission conduction load

Compute conduction component through opaque walls, roof, and glass:

$$QT = \frac{\sum_{i=1}^{N_{surf}} A_i U_i (t - t_i)}{A_F}$$

where

QT = conduction component of load
A_i = surface area for surface i
U_i = overall U-value for surface i
t = bin temperature
t_i = inside air temperature

Surface	Area	×	U	=	AU
N-WALL	900		0.0684	=	61.56
E-WALL	600		0.0684	=	41.04
S-WALL	900		0.0684	=	61.56
W-WALL	600		0.0684	=	41.04
ROOF	5424		0.0807	=	437.72
GLASS	3000		0.97	=	2910.00
			TOTAL	=	3552.92 Btu/h·°F

$$QT = 3552.92\,(t - t_i)/12{,}000$$
$$= 0.2961\,(t - t_i)$$

With t_i set to 75°F, this becomes

$$QT = 0.2961t - 22.208\ (Btu/h \cdot ft^2)$$

When the space is unoccupied, the night setback temperature is 55°F. Therefore, during this period, the conduction through walls, roof, and glass is:

$$QT = 0.2961t - 16.28\ (Btu/h \cdot ft^2)$$

(f) Perimeter zone internal loads

$$\text{Internal Loads} = \frac{\text{Use Factor} \cdot \text{Maximum Load} \cdot \text{Heat Factor}}{A_F}$$

where

Use Factor = average usage during occupied or unoccupied periods, expressed as fraction of maximum load
Maximum Load = connected load for lighting and other internal equipment or, for people, maximum number of occupants
Heat Factor = factor for converting unit of load to Btu/h/(3.41 Btu/h = 1 W)

Period			Load, Btu/h·ft²
Occupied period (0700 to 1900)			
Lights	2.5 × 3.41 × 0.8 × 5424/12,000	=	3.08
Equipment	1.0 × 3.41 × 5424/12,000	=	1.54
Occupants, sensible	(255/100) (5424/12,000)	=	1.15
Total sensible		=	5.77
Occupants, latent	(255/100) (5424/12,000)	=	1.15
Unoccupied period (1900 to 0700)			
Lights	0.25 × 3.41 × 0.8 × 5424/12,000	=	0.31
Equipment			0.00
Occupants			0.00
Total sensible			0.31

(g) Total perimeter zone loads. The total space load for the perimeter zone is the sum of contributions from all the components at a given outdoor temperature. Therefore, the load profile can be expressed as a sum of linear equations described above:

Occupied		*Unoccupied*	
QSOL	= 0.03906 t + 2.1799	QSOL	= 0.03906 t + 2.1799
QTS	= 0.00542 t + 0.1028	QTS	= 0.00542 t + 0.1028
QT	= 0.2961 t − 22.208	QT	= 0.2961 t − 16.28
QI	= 5.77	QI	= 0.31
QTOT	= 0.3406 t − 14.1553	QTOT	= 0.3406 t − 13.6873

3. *Interior zone diversified loads*

(a) Solar heat gain through glass—none.
(b) Transmission solar loads component. Compute solar component through opaque roof. This zone has no exterior walls.

$$QTS = \frac{A_R U_R \cdot CLTDS \cdot K \cdot FPS}{A_F}$$

Month	Surface	Area ×	U	× CLTDS ×	K ×	FPS	
July	Roof	6576	0.0807	22	1	0.64	= 7472
QTS,Jul = 7472/12,000 = 0.622							
Jan	Roof	6576	0.0807	3	1	0.44	= 700.5
QTS,Jan = 700.5/12,000 = 0.0584							

Linearize solar contribution from the roof:

$$QTS = 0.00593\,t + 0.0465\ Btu/h \cdot ft^2$$

(c) Compute transmission load due to conduction from roof

$$QT = \frac{6576 \times 0.0807}{12{,}000}(t - t_i) = 0.04422\,(t - t_i)$$

For the occupied period (t_i = 75°F) and the unoccupied period (t_i = 55°F). The transmission profile becomes

$$QT = 0.04422\,t_o - 3.3165\ (\text{occupied})$$

$$QT = 0.04422t_o - 2.4321\ (\text{unoccupied})$$

(d) Interior Loads

Period			Load, Btu/h·ft²
Occupied period (0700 to 1900)			
Lights	(2.5 × 3.74) (3.41 × 0.8 × 6576/12,000)	=	3.81
Equipment	1 × 3.41 × 6576/12,000	=	1.87
Occupants, sensible	(255/100) (6576/12,000)	=	1.40
Total sensible			7.01
Occupants, latent	255/100 × 6576/12,000		1.40
Unoccupied period (1900 to 0700)			
Lights	0.25 (3.41 × 0.8 × 6576/12,000)	=	0.37
Equipment		=	0.00
Occupants		=	0.00
Total sensible		=	0.37

(e) Total interior zone loads
Compute the total space load for the interior zone by summing the individual components. The load profile can be expressed as a sum of linear equations.

Occupied		*Unoccupied*	
QTS	= 0.00593 t + 0.0465	QTS	= 0.00593 t + 0.0465
QT	= 0.04422 t − 3.3165	QT	= 0.04422 t − 2.4321
QI	= 7.01	QI	= 0.37
$QTOT_{occ}$	= 0.0502 t + 3.740	$QTOT_{unocc}$	= 0.0502 t − 2.015

where t is the outside air temperature.

4. *Determine HVAC system performance*
The following calculation steps lead to completion of noted columns in Table 6.

Column A. Obtain bin temperature weather data (ASHRAE 1984 or USAF 1978).

Column B. Compute outside air humidity ratio OAW from outside air dry-bulb and mean coincident wet-bulb bin data using a psychrometric chart or relationships in Chapter 6.

Table 6 Coil Loads Summary (Example 3)

Variable Description and Units for Columns A through N

A	Outside air bin dry-bulb temperature	°F	H	Mixed air humidity ratio	lb_w/lb_a
B	Outside air humidity ratio of water vapor to dry air	lb_w/lb_a	I	Cooling coil leaving air humidity ratio	lb_w/lb_a
C	Supply air volume	cfm/ft^2	J	Preheat coil load	$Btu/h \cdot ft^2$
D	Mixed air dry-bulb temperature	°F	K	Cooling coil sensible load	$Btu/h \cdot ft^2$
E	Cooling coil leaving air dry-bulb temperature	°F	L	Cooling coil latent load	$Btu/h \cdot ft^2$
F	Preheat coil leaving air dry-bulb temperature	°F	M	Cooling coil total load	$Btu/h \cdot ft^2$
G	Return air humidity ratio	lb_w/lb_a	N	Baseboard heating load	$Btu/h \cdot ft^2$

$$OAW = f(OADB, MCWB)$$

Column C. For a VAV system operating with a constant supply air temperature, determine the required air volume based on the load profiles developed earlier. The supply air quantity VSA is calculated as a function of outside air for a particular design supply air temperature difference Δt.

$$\Delta t = 75 - 55 = 20\,°F \text{ (occupied period)}$$

Perimeter zone:

$$VSA = \frac{\text{Load}}{60\,\rho\,c_p\,\Delta t} = \frac{\text{Load}}{1.1\,\Delta t}$$

$$VSA = (0.3406\,t - 14.1553)/(1.1 \times 20) = 0.0155t - 0.6434 \ (cfm/ft^2)$$

If VSA less than 0.2 cfm/ft^2 (5424/12000) = 0.0904, set VSA = 0.0904

Interior zone:

$$VSA = (0.0502\,t + 3.74)/(1.1 \times 20)$$
$$= 0.0023\,t + 0.1700\ cfm/ft^2$$

If VSA is less than 0.2 cfm/ft^2 (6576/12000) = 0.1096, set VSA = 0.1096

Total supply air volume:

$$VSA = VSA\ (perimeter) + VSA\ (interior)$$

During unoccupied periods, the system is assumed to be off. Therefore, VSA = 0.

Column D. Compute mixed air dry-bulb temperature (MADB, Col. D) from air energy balance on the outside air mixing box.

$$MADB = RADB + (VO/VSA)(OADB - RADB)$$

where

RADB = return air dry-bulb temperature; assumed constant at 75 °F during occupied periods, 55 °F during unoccupied periods
VO = outside air volume; assumed constant 0.20 cfm/ft^2 during occupied hours, 0 otherwise
VSA = total supply air volume (Col. C)
OADB = outside air dry-bulb temperature; bin value (Col. A), same as t above

thus

$$\begin{aligned} MADB &= 75 + (0.20/VSA)(OADB - 75) \text{ (occupied)} \\ &= 55 \text{ (unoccupied)} \end{aligned}$$

Column E. Compute cooling coil leaving air dry-bulb temperature CCLADB as the required supply air temperature minus the fan temperature rise (assumed constant at 2 °F).

$$CCLADB = 55 - 2 = 53\,°F$$

More accurate models would calculate the fan temperature rise at part-load conditions.

Column F. Compute preheat coil leaving air dry-bulb temperature. If MADB less than CCLADB, set PHLADB = CCLADB; otherwise set PHLADB = MADB.

Column G. Compute return air humidity ratio RAW, which is essentially the cooling coil leaving air humidity ratio plus any latent heat gain from the spaces.

$$RAW = QL/(4840\ VSA) + CCLAW$$

where

QL = total latent heat gain; assumed constant at 2.55 Btu/h · ft^2 because of people

CCLAW = cooling coil leaving air humidity ratio; (Col. I) assumed constant at 0.0077 lb_w/lb_a when the coil is wet for the coil model used in this example. When the coil is not operating, the humidity ratio will not have this value, and an iteration is performed to determine the true system humidity ratios.

Thus $RAW = 0.0077 + 0.00053/VSA$

Column H. Compute mixed air humidity ratio MAW from an energy balance on the outside air mixing box.

$$MAW = RAW + (VO/VSA)(OAW - RAW)$$

Column I. Cooling coil leaving air humidity ratio discussed under G.

Column J. Compute preheat coil load.

$$QPHC = (1.1\ VSA)(PHLADB - MADB)$$

Column K. Compute cooling coil sensible load.

$$QCS = (1.1\ VSA)(MADB - CCLADB)$$

Column L. Compute cooling coil latent load.

$$QCL = (4840\ VSA)(MAW - CCLAW)$$

Column M. Compute cooling coil total load.

$$QCT = QCS + QCL$$

Column N. Compute baseboard heating load QHC. If a heating load exists (the net load on the space is negative), the supply air volume is set to minimum value. Therefore, baseboard heating must account for the overcooling because of this supply air as well as the sensible load on the space.

Thus, for the *occupied period*:

Perimeter zone

$$\begin{aligned} QHC &= -(0.3406\,t - 14.1553) + 1.1 \times 0.0904 \times 20 \\ &= 16.14 - 0.3406\,t \end{aligned}$$

Interior zone

$$\begin{aligned} QHC &= -(0.0502\,t + 3.74) + 1.1 \times 0.1096 \times 20 \\ &= -1.3228 - 0.0502\,t \end{aligned}$$

Total

$$QHC = QHC\,(perimeter) + QHC(interior)$$

For the unoccupied period during which $t_i = 55\,°F$, the supply air is zero. For the perimeter zone, an outside air load term is added to account for infiltration (0.05 cfm/ft^2):

Perimeter zone

$$\begin{aligned} QHC &= 0.3406\,t - 13.6829 + 1.1 \times 0.05 \times (t - t_o) \\ &= 0.3956\,t - 16.7079 \end{aligned}$$

Interior zone

$$QHC = 0.0502\,t - 2.015$$

If, for either zone, QHC < 0, set QHC = 0.

Table 6 summarizes the coil load calculation for both occupied and unoccupied periods. Annual energy consumption can be found from the loads in Table 6 by applying fan, chiller, and boiler part-load characteristics. An example of the calculation for this problem is contained on page 28.17 in the 1989 ASHRAE *Handbook—Fundamentals* (I-P edition).

OTHER ENERGY CONSIDERATIONS

Energy Conservation Effects

Studies of the energy conservation effects from wintertime thermostat setback, summertime thermostat setup, and night setback for electric, gas, or oil furnaces and heat pumps are listed in the bibliography. Predicted energy savings up to 50% for combined setbacks are reported and are shown to be a strong function of outdoor design temperatures, number of degree days, residential construction, and type of heating unit. Typical annual heating energy savings for a 4 °F winter setback range between 14 and 20%; typical annual heating energy savings for a 10 °F winter nighttime setback for an 8 h/day range, between 7 and 12%. Typical seasonal energy savings for residential cooling units for a 3 °F temperature setup in summer are between 15 and 30%.

Shavit (1975) reports savings from increased relative humidity during winter operation. Savings that might be realized from electric ignition and/or automatic vent dampers on gas and oil furnaces are reported by AGA (1977), Zabinski and Loverme (1974), and Macriss and Elkins (1976). Annual energy savings reported for a combination of an intermittent ignition device and an automatic vent-damper range between −16 and +40%, with a mean reduction in gas consumption of 10% (AGA 1977).

Threlkeld and Jordan (1954), Yellott and Ewing (1976), Beckman *et al.* (1977), and Yellott (1972) report savings during the cooling season from applying sunscreens and/or attic ventilation. Sunscreens yield cooling energy savings ranging from negligible to 25% for typical residential applications, while attic ventilation has resulted in cooling energy savings ranging from negligible to 9% for specific applications.

Thermal Mass Effects

Burch *et al.* (1984a, 1984b), Robertson and Christian (1985), Childs *et al.* (1983), and Arumi-Noe (1984) in studies in Maryland and New Mexico show that the massiveness of an exterior wall reduces the heating and cooling requirements of buildings, provided the room air temperature floats above the thermostat set point in heating and below the thermostat set point in the cooling season. Robertson and Christian (1985) found 2 to 4% reductions. The floating temperatures occur more frequently in mild climates and during the spring, summer, and fall. In periods where the room air temperature did not float (during the winter), steady-state analysis accurately calculated the net energy transfer in the 20 by 20-ft test buildings (U-values and outdoor temperatures averaged over several days) during the winter. Steady-state analysis underestimated the amount of energy required by the lightweight buildings during spring, summer, and fall. The energy requirement of the heavyweight test buildings could be more accurately quantified by steady-state analysis during all four seasons.

Burch *et al.* (1986) modeled the annual space heating and cooling loads of a typical house operated with fixed thermostat settings and found interior mass features (partition walls and interior furnishings) had only a small effect on the annual space heating and cooling loads, except when the house operated near its balance-point temperature.

Buildings with low balance-point temperature (with large solar or internal gains) experience more room air temperature floating in winter. This sensitivity of energy use to the mass of building components could cause lightweight buildings to use more energy than that predicted by a steady-state analysis for the winter.

Location of the mass in relation to the conditioned space and the insulation has a large effect on the deviation between measured energy use and steady-state analysis. In heavyweight buildings where mass was outside the insulation, the measured energy use closely matched that predicted by steady-state analysis. However, when the insulation was outside the mass, the energy use was greater than that predicted by steady-state analysis. Although Christian and Downing (1986) developed simplified procedures to estimate the effect of thermal mass in reducing heating and cooling loads in various climates, more research is needed to develop generalized thermal mass credits for load reduction.

CORRELATION METHODS

Even with simplified multiple-measure methods, manual estimation of the energy requirements of intermediate (20,000 to 50,000 ft^2) or large (> 50,000 ft^2) commercial or institutional buildings can be complex and time-consuming. Properly using the bin method for large buildings normally requires subdividing the building into several thermal zones and calculating loads for each. The loads can then be used to perform a system simulation to obtain equipment loads, which in turn are used with the equipment characteristics to obtain the equipment energy requirements. Since these calculations must be performed at each temperature bin point and the calculations may have to be repeated for alternative designs, the total effort required to perform a comparative energy analysis may be great.

One way of simplifying the analysis is to develop correlations that relate energy requirements to various input parameters. Correlations are typically developed by performing many detailed analyses and using statistical means to reduce the results to a simple form. That form is typically an equation, easy to use in a calculator or small computer program, or a graph that is convenient to use manually and provides quick insight into the basic input/output relationships of the energy requirements.

Sud *et al.* (1979) indicate that graphical procedures simplify annual energy requirements estimates for intermediate and large commercial and institutional buildings. The information required can provide relatively reliable results without laborious manual calculations. This method is based on three sets of graphs that correspond to the three elements of any energy estimating method: (1) space load, (2) secondary equipment load, and (3) primary equipment energy requirements. A separate set of graphs is required for each weather zone, building type, and size range and HVAC system type. Parameters used in the graphs include: (1) high or low minimum ventilation rates for three types of economizer cycles, (2) high or low interior loads with combinations of high or low thermostat settings, and (3) continuous or setback HVAC system operation. Plant operation, and thus equipment energy requirements, are characterized by an annual equivalent coefficient of performance for generic heating and cooling equipment. The sum of HVAC equipment, auxiliary equipment and lighting, and internal load energy use determines the total annual building energy use.

Two other correlation methods, *f*-Chart for active solar systems and SLR for passive space heating, are described later. Although the name indicates a graphic method, note that *f*-Chart also provides equations for the correlations.

The accuracy of correlation methods depends on the size and accuracy of the database and the appropriateness of the statistical means used to develop the correlation. A database generated from measured data can lead to accurate correlations (Lachal 1992). The key to the proper use of a correlation is that the case being studied matches the cases used in developing the database. Inputs to the correlation (the independent variables) indicate the factors that are considered to have significant impact on energy consumption. The use of a correlation is invalid when either an input parameter is used beyond its valid range (corresponding to extrapolation rather than interpolation), or when some important feature of the building/system is not included in the available inputs to the correlation. When designers wish to analyze such features, they must find another method of analysis. The most flexible methods are detailed dynamic simulations.

DYNAMIC METHODS

Because of the wide-ranging and constantly changing internal and external factors that determine thermal loads on commercial and industrial buildings, frequent evaluation is needed to obtain reasonably accurate estimates of annual energy consumption. High peak internal heat loads in many commercial buildings necessitate a review of these load patterns hourly and for each different type of day during the year.

To apply these methods, a mathematical model of the building and its energy systems must represent (1) the thermal behavior of the building structure (the loads model), (2) the thermodynamic behavior of the air-conditioning delivery system (the secondary systems model), and (3) a mathematical relationship for load versus energy requirements of the primary energy conversion equipment (the plant model). Usually, each model is formulated so that input quantities allow calculation of output quantities. For example, weather and internal load information are inputs to the loads model, allowing calculation of sensible loads on the occupied spaces in the building. Most often, several thermally different zones within the building must be modeled rather than one representing the building as a whole.

The secondary system model is comprised of conservation equations (mass and energy) for each component of the actual system, *e.g.*, heating coils, cooling and dehumidifying coils, mixing boxes, and fans. These can usually be arranged to allow calculation of the required rate of energy delivery to the heating and cooling coils for a given space sensible load, previously calculated by the loads model. In an actual simulation, there may be several secondary system models, each representing a physical delivery system serving a group of zones.

The plant model relates the required input energy rate, *e.g.*, gas and/or electrical power, to the required energy rates of several secondary systems. Typically, a central plant model includes such relationships for chillers, boilers, cooling towers, and so forth.

Figure 8 shows the basic function of each major model element on an input and/or output basis. The control interaction path shows that capacity limits and/or control characteristics of the air-conditioning system can affect the space load. Therefore, any

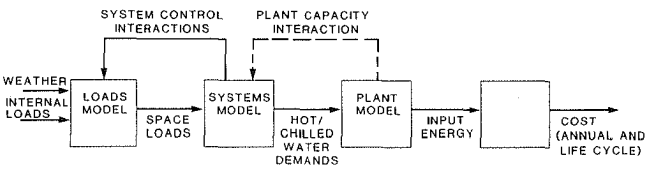

Fig. 8 Flow Diagram for Calculating Hourly Heating Cooling Loads Using ASHRAE Algorithms

variation in space temperature allowed by the system causes the space sensible load to vary. Capacity limits and control characteristics of the central plant can cause variation in secondary system performance, thus affecting loads as shown by the dashed lines in Figure 8.

Figure 8 shows an economic model that calculates energy costs (and sometimes capital costs) based on the estimated required input energy. Thus, the simulation model calculates energy usage and cost for any given input weather and internal loads. By applying this model (*i.e.*, determining output for given inputs) at each hour (or other suitable interval), the hour-by-hour energy consumption and cost can be determined. Maintaining running sums of these quantities yields monthly or annual energy usage and costs.

These models only compare design alternatives; a large number of uncontrolled and unknown factors usually precludes the use of such models for accurate prediction of utility bills. The bibliography lists several models. Generally, the loads model tends to be the most complex and time-consuming; the central plan model, the least.

CALCULATING INSTANTANEOUS SPACE SENSIBLE LOAD

Calculating instantaneous space sensible load is a key step in any building energy simulation. The *heat balance method* and the *weighting factor method* are two widely used methods for these calculations.

The *instantaneous space sensible load* is the rate of heat flow into the space air mass. This quantity, sometimes called the cooling load, differs from heat gain in that the latter usually contains a radiative component that passes entirely through the air mass and is absorbed by other bounding surfaces. Instantaneous space sensible load is entirely convective; even loads from internal equipment, lights, and occupants enter the air by convection from the surface of such objects or by convection from room surfaces that have absorbed the radiant component of energy emitted from these sources. However, some adjustment must be made when radiant cooling and heating systems are evaluated because a portion of the space load is offset directly by radiant transfer without convective transfer to the air mass.

For equilibrium conditions, the instantaneous space sensible load must be matched by the heat removal rate of the conditioning equipment. Any imbalance in these rates changes the energy stored in the air mass. Customarily, however, the thermal mass (heat capacity) of the air itself is ignored in the analysis, so that the air is always assumed to be in thermal equilibrium. Under these assumptions, the instantaneous space sensible load and the rate of heat removal are equal in magnitude and opposite in sign.

In sensible load calculations, the cooling situation is often the reference frame. If there is heat *loss*, only the algebraic signs change. Therefore, discussion of the heating situation is omitted when developing mathematical models that work equally well for either situation.

Weighting and response factors and conduction transfer functions all stem from the same mathematical treatment (discreet convolution), but each represent a different concept. *Weighting factors*, also called room response factors, are used in the weighting factor method to calculate space instantaneous sensible load components from corresponding heat gain components. *Response factor* and *conduction transfer functions*, on the other hand, refer to conductive heat transfer (*e.g.*, through walls and floors) and are used to calculate the transmission component of heat gain (see Chapter 26).

Note that both the weighting factor method and the heat balance method conduction transfer functions (or their equivalents) are used to calculate transmission heat gain or loss. The principal difference is in the methods used to calculate the subsequent internal heat transfers to the room. Experience with both methods has indicated largely the same results, provided the weighting factors are determined for the specific building under analysis.

Heat Balance Method

The heat balance method for calculating net space sensible loads is the more fundamental of the two methods. Its development relies on the first law of thermodynamics (conservation of energy) and the principles of matrix algebra. Since it requires fewer assumptions than the weighting factor method, it is also more flexible. However, the heat balance method requires more calculations at each point in the simulation process, using more computer time. The weighting factors used in the weighting factor method are determined by the heat balance equations in a form similar to the one presented here. And, although not necessary, linearization is commonly used to simplify the radiative transfer formulation.

The heat balance method allows the net instantaneous sensible heating and/or cooling load to be calculated on the space air mass. Generally, a heat balance equation is written for each enclosing surface, plus one for room air. This set of equations can then be solved for the unknown surface and air temperatures. Once these temperatures are known, they can be used to calculate the convective heat flow to or from the space air mass.

To write heat balance equations, consider a space within the building under analysis as an enclosure bounded by a number of discrete surfaces (walls, floors, windows, and ceiling). At any time θ, each of these surfaces is assumed to be at some uniform temperature $t_{i,\theta}$. Also, the space air mass is assumed to be of uniform temperature $t_{a,\theta}$. At any plain boundary, the flux entering the boundary must equal the flux leaving the boundary. Thus, at the inside surface of any room wall, the heat flow into the surface—because of convection from room air, radiation from interior sources such as lights and people, and the net radiant interchange between the wall and all other surfaces in the room—is exactly balanced by the conductive flux leaving the surface to penetrate the solid.

When radiant cooling and heating systems are evaluated, the radiant source should be identified as a room surface. The calculation procedure considers the radiant source in the heat balance analysis. Therefore, this method is preferred over the weighting factor method evaluating radiant systems.

Similarly, for the outside surface of an exterior wall, the conductive flux leaving the surface to penetrate the solid toward the room is exactly balanced by absorbed solar radiation, net longwave radiant flux from the surroundings, and convective flux from the outdoor air. A heat balance on the room air volume requires the air-conditioning system to remove the net heat added to the volume by *convection* from interior surfaces and interior heat sources (lights, people) and by mass transfer due to infiltration.

Thus, at the *ith* surface at time θ, the energy (per unit area) balance, is

$$q_{i,\theta} = h_i (t_{a,\theta} - t_{i,\theta}) + \sum_{k=1}^{n} g_{i,k} (t_{a,\theta} - t_{i,\theta}) + R_i \qquad (27)$$

where the first term represents heat gain due to convection from the room air, the summation represents radiative interchange (longwave), and the last term R_i represents all other radiant energy absorbed by the surface. The last term includes shortwave radiation from lights, window solar gain, and the radiant component of occupant and equipment loads.

The left side of Equation (27) $q_{i,\theta}$ represents the *net* transfer to the surface from the air and surroundings. It must be exactly matched by the heat conducted into the solid surface. The latter

can be represented in terms of historical values of surface temperatures and heat flux using conduction transfer functions (ASHRAE 1976). [Response factor and conduction transfer functions are *closely* related, elegant solutions to the transient one-dimensional, multilayered-slab heated conduction problem. Mitalas and Stephenson (1967), Mitalas (1968), and Kusuda (1969) give several theoretically equivalent solutions, and at least two forms appear in Chapters 22 and 26.]

$$q_{i,t} = \sum_{j=0}^{m} X_j t_{i,\theta-j} - \sum_{j=0}^{m} Y_j t_{oi,\theta-j} + CR_i q_{i,\theta-j}$$

$$= X_o t_{i,\theta} + \sum_{j=1}^{m} X_j t_{i,\theta-j} - \sum_{j=1}^{m} Y_j t_{oi,\theta-j} + CR_i q_{i,\theta-j} \quad (28)$$

By substituting Equation (28) into Equation (27), $q_{i,t}$ can be eliminated, and after rearrangement

$$\left(X_o + h_i + \sum_{k=1}^{m} g_{i,k}\right) t_{i,\theta} - \sum_{k=1}^{m} g_{i,k} t_{k,\theta} - h_i t_{a,\theta} =$$

$$- \sum_{j=1}^{m} X_j t_{i,\theta-j} + \sum_{j=0}^{m} Y_j t_{oi,\theta-j} + CR_i q_{i,\theta-1} + R_i \quad (29)$$

In addition to the n equation forms of Equation (29), a heat balance equation also can be written for the space air. Assuming negligible heat capacity of this air relative to the more massive building elements, the sum of all heat flow to it must be zero, yielding

$$\sum_{j=1}^{n} S_j h_j (t_{j,\theta} - t_{a,\theta}) + m_1 c_p (t_{oa,\theta} - t_{a,\theta})$$
$$+ QI_\theta + QS_\theta = 0 \quad (30)$$

Here, the summation represents convective transfer from the enclosing surfaces, second-term infiltration QI_θ, convective transfer from internal objects, and QS_θ, the rate of energy addition and/or removal by the space-conditioning equipment. This equation can be rearranged to give

$$\sum_{j=1}^{n} S_j h_j (t_{j,\theta} - t_{a,\theta}) - m_1 c_p t_{a,\theta} =$$
$$m_1 c_p t_{oa,\theta} - QI_\theta - QS_\theta \quad (31)$$

Equations (29) and (31) together represent a set of $n + 1$ equations in $n + 1$ unknown temperatures. The equations are arranged so that all unknowns are on the left, and all known quantities are on the right. This facilitates rewriting the problem to be solved in vector-matrix notation as

$$At_\theta = B \quad (32)$$

where A is an $n + 1$ by $n + 1$ matrix, and B is a $(n + 1)$ vector. By convention, the first n elements of the t_θ vector are the surface temperatures, while the $n + 1$ element is the air temperature.

The elements of A and B can be determined from the expanded equations given previously. The first n diagonal elements of A are

$$a_{ii} = X_o + h_i + \sum_{k=1}^{n} q_{i,k};\ i = 1, n \quad (33)$$

while the last diagonal element is

$$a_{n+1,n+1} = -\left(\sum_{k=1}^{n} S_k h_k + m_1 c_p\right) \quad (34)$$

and off-diagonal elements are

$$a_{i,j} = -g_{i,j};\ i,j = 1, n \quad (35)$$

$$a_{i,n+1} = -h_i;\ i = 1, n \quad (36)$$

$$a_{n+1,j} = S_j h_j;\ j = 1, n \quad (37)$$

The elements of B are the terms on the right of Equations (29) and (31).

Through these equations, the heat transfer at any surface is coupled to heat transfer at all other surfaces and to heat transfer to or from the room air. The heat transfer at an inside wall surface, for example, is coupled to the heat transfer at the outside surface through conduction transfer functions for the wall. It is coupled to the heat transfer at all other inside surfaces through equations governing intersurface radiant exchange, and it is coupled to the room air volume through the inside surface convection coefficient. The radiant and convective fluxes from solar effects and the effects of interior energy sources can be calculated independently, so that an equation for the flux at any surface in terms of the surface temperature, the temperature of all other surfaces, and the room air temperature can be written (assume that all *past* temperatures and fluxes are known).

The heat balance method requires that Equation (28) be solved for surface and air temperatures at each point, allowing subsequent calculation of sensible load. The solution can be derived by various mathematical methods, some more efficient than others. As discussed by Sowell and Walton (1980), computational speed can be increased by using the special properties of the coefficient matrix A.

Regardless of the solution method, the procedure is to compute updated values of the right vector B and then solve for t_θ. Note that B involves (1) historical values of all surface temperatures, (2) historical values of the outside surface temperatures, (3) the previous value of heat flux at each surface, (4) outside air temperature, (5) the absorbed shortwave radiant flux at each surface, (6) the internal load, and (7) the supply heating and/or cooling effect.

Historical data are developed and retained as the solution progresses, starting with some assumed initial conditions and past performance. Internal loads are usually calculated from schedules of occupancy, lighting, and equipment usage. The radiant absorption at each surface is usually approximated by uniformly distributing window solar load and known radiant components of lighting, equipment, and occupants to each unit area of walls, ceiling, and floor.

Outside surface temperatures can be found by writing a heat balance at each outside surface. This produces an equation similar to Equation (27), equating heat flux into the solid material to the algebraic sum of convection from outdoor air, longwave radiant absorption from the sky and surroundings, and shortwave solar absorption. The resulting equations, one for each outside surface, can be rearranged to give an expression for the outside surface temperatures, shown in Equation (38).

$$t_{oi,\theta} = (q_{si,\theta} + q_{li,\theta} + h_o t_{oa,\theta} + \sum_{j=0}^{m} Y_i t_{i,\theta-j}$$
$$- \sum_{j=1}^{m} Z_j t_{oi,\theta-j} + CR\, q_{oi,\theta-1})/(h_o + Z_o) \quad (38)$$

Here, $q_{si,t}$ and $q_{li,t}$ represent the net short- and longwave radiant flux at the *ith* outside surface at time t, while h_o is the outside film coefficient. It is important to note that the right side of Equation (38) contains the *inside* surface temperature at time θ; thus this set of equations must be solved simultaneously with Equation (32). However, since this would double the size of the overall heat balance problem, significantly increasing computer memory requirements and solution time, a simplified assumption is often made. For example, some algorithms simply use the outside surface temperature from the *previous* time step when evaluating the right side of Equation (28). Resulting errors are thought to be small for thermally massive elements. For lightweight walls, however, the equations should probably be solved simultaneously.

The supply heating and/or cooling term in Equation (31) QS_θ presents a similar dilemma. Because of the thermostat and the nature of the air-conditioning process, QS_θ depends on room temperature $t_{a\theta}$, which is one of the unknowns in Equation (32). This requires some type of simultaneous solution procedure for Equation (32) and the space control characteristic, *e.g.*, Figure 9. Iteration is usually employed to find a space temperature and supply heating and/or cooling amount that simultaneously satisfies the heat balance equations and the control characteristics.

In principle, the method described above extends directly to multiple spaces. An equation such as Equation (32) can be written for each space; this recognizes that the outside of partitions are in fact the inside surfaces of adjacent spaces. In practice, however, the size of the coefficient array required for solving the simultaneous equations becomes prohibitively large, and the solution time excessive. For this reason, many programs solve only one space at a time and assume that the adjacent space temperatures are either the same as the space in question or some assigned, constant value. Other approaches may remove this limitation (Walton 1980).

Weighting Factor Method

The weighting factor method of calculating instantaneous space sensible load is a simple but flexible technique that accounts for the important parameters affecting building energy flow. It represents a compromise between simpler methods, such as a steady-state calculation that ignores the ability of building mass to store energy, and more complex methods, such as complete energy balance calculations. With this method, space heat gains at constant space temperature are determined from a physical description of the building, the ambient weather conditions, and internal load profiles. Along with the characteristics and availability of heating and cooling systems for the building, these space heat gains are used to calculate air temperatures and heat extraction rates. This discussion is in terms of heat gains, cooling loads, and heat extraction rates. Heat losses, heating loads, and heat addition rates are merely different terms for the same quantities when the direction of heat flow is reversed, *i.e.*, when the quantity has the opposite algebraic sign.

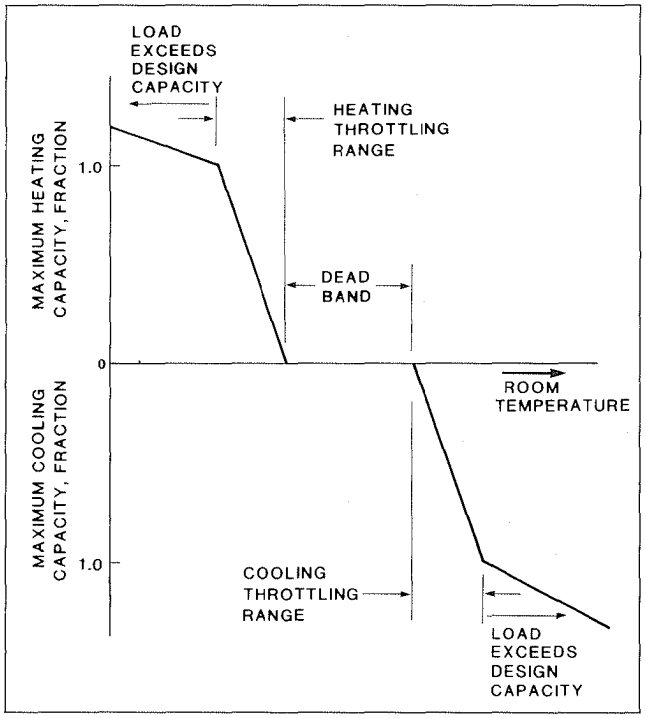

Fig. 9 Thermostat Model of Proportional Control with Deadband and Dual Throttling Ranges

The weighting factors represent Z-transfer functions. The Z-transform is a method for solving differential equations that is used with discrete data. Two groups of weighting factors are used: heat gain and air temperature. Heat gain weighting factors represent transfer functions that relate space cooling load to instantaneous heat gains. A set of weighting factors is calculated for each group of heat sources that differ significantly in (1) the relative amounts of energy appearing as convection to the air versus radiation, and (2) in the distribution of radiant energy intensities on different surfaces.

Air temperature weighting factors represent a transfer function that relates room air temperature to the net energy load of the room. The weighting factors for a particular heat source are determined by introducing a unit pulse of energy from that source into the room's network. The network is a set of equations (described in the previous section) that represents a heat balance for the room. At each time step (1-h intervals), including the initial introduction, the energy flow to the room air represents the amount of the pulse that becomes a cooling load. Thus a long sequence of cooling loads can be generated from which the weighting factors are calculated. Similarly, a unit pulse change in room air temperature can be used to produce a sequence of cooling loads.

A two-step process is used to determine the air temperature and heat extraction rate of a room or building zone for a given set of conditions. First, the room's air temperature is assumed to be fixed at some reference value. This reference temperature is usually chosen as the average air temperature expected for the room over the simulation period. Instantaneous heat gains are calculated based on this constant air temperature. Various types of heat gains are considered. Some, such as solar energy entering through windows or energy from lighting, people, or equipment, are independent of the reference temperature. Others, such as conduction through walls, depend directly on the reference temperature.

A space sensible cooling load for the room, defined as the rate at which energy must be removed from the room to maintain the reference value of the air temperature, is calculated for each type of instantaneous heat gain. The cooling load generally differs from the instantaneous heat gain because some of the energy from the heat gain can be absorbed by walls or furniture and stored for later release to the air. At hour t, the calculation employs present and past values of the instantaneous heat gain (q_θ, $q_{\theta-1}$), past values of the cooling load ($Q_{\theta-1}$, $Q_{\theta-2}$, . . .), and the heat gain weighting factors (v_0, v_1, v_2, . . . w_1, w_2, . . .) for the type of heat gain under consideration. Thus, for each type of heat gain q_θ, the cooling load Q_θ is calculated as:

$$Q_\theta = v_0 q_\theta + v_1 q_{\theta-1} + \ldots - w_1 Q_{\theta-1} - w_2 Q_{\theta-2} \ldots \quad (39)$$

The heat gain weighting factors incorporate information about the room and the heat gain source. They are a set of parameters that quantitatively determine how much of the energy entering a

room is stored and how rapidly the stored energy is released during later hours. Mathematically, the weighting factors are parameters in a Z-transfer function relating the heat gain to the cooling load (ASHRAE 1976).

These weighting factors differ for different heat gain sources because the relative amounts of convective and radiative energy leaving various sources differ, and because the distribution of radiative energy can differ. The heat gain weighting factors also differ for different rooms because room construction influences the amount of incoming energy stored by walls or furniture and the rate at which it is released. After the first step, the cooling loads from various heat gains are added to give a total cooling load for the room.

In the second step, the total cooling load is used—along with information on the heating, ventilating, and air-conditioning system attached to the room, and a set of *air temperature weighting factors*—to calculate the actual heat extraction rate and air temperature. The actual heat extraction rate differs from the cooling load because, in practice, the air temperature can vary from the reference value used to calculate the cooling load or because of HVAC system characteristics. The deviation of the air temperature from the reference value at hour θ, t_θ, is calculated as:

$$t_\theta = 1/g_o [(Q_\theta - ER_\theta) + P_1 (Q_{\theta-1} - ER_{\theta-1}) + P_2 (Q_{\theta-2} - ER_{\theta-2}) + \ldots - g_1 t_{\theta-1} - g_2 t_{\theta-2} - \ldots] \quad (40)$$

where ER_θ is the energy removal rate of the HVAC system at hour θ, and $g_0, g_1, g_2, \ldots, P_1, P_2, \ldots$ are the air temperature weighting factors, which incorporate information about the room, particularly the thermal coupling between the air and the storage capacity of the massive elements.

Tables of values of weighting factors for typical building rooms are presented in Chapter 26. One of the three groups of weighting factors, for light, medium, and heavy construction rooms, can be used to approximate the behavior of any room. Some automated simulation techniques allow weighting factors to be calculated specifically for the building under consideration (LBL 1981). This option improves the accuracy of the calculated results, particularly for a building with an unconventional design.

Two general assumptions are made in the weighting factor method. First, the processes modeled are linear. This assumption is necessary because heat gains from various sources are calculated independently and summed to obtain the overall result (*i.e.*, the superposition principle is employed). Therefore, nonlinear processes, such as radiation or natural convection, must be approximated linearly. This assumption does not represent a significant limitation, because these processes can be linearly approximated with sufficient accuracy for most calculations. The second assumption is that system properties influencing the weighting factors are constant, *i.e.*, they are not functions of time. This assumption is necessary because only one set of weighting factors is used during the entire simulation period. This assumption can limit the use of weighting factors in situations where important room properties vary during the calculation. Two examples are the distribution of solar radiation incident on the interior walls of a room that can vary hourly, and inside surface heat transfer coefficients.

When the weighting factor method is used, a combined radiative-convective heat transfer coefficient is used as the inside surface heat transfer coefficient. This value is assumed constant even though in a real room the radiant heat transferred from a surface depends on the temperature of other room surfaces (not on the room air temperature) and the combined heat transfer coefficient is not constant. Under these circumstances, an average value of the property must be used to determine the weighting factors. Cumali *et al.* (1979) have investigated extensions to the weighting factor method to eliminate this limitation.

SIMULATING SECONDARY SYSTEMS

Secondary system models mathematically relate the rate of heating and/or cooling energy delivery, *e.g.*, hot and/or chilled water, to space sensible loads. Usually, such models are formulated to receive the space sensible loads as input and allow calculation of heating and/or cooling rates at the coils (also see the section Overall Modeling Strategies).

Fundamental Relations for Moist Air

The underlying principles for secondary system models are primarily those for mass and energy balances on moist air described in Chapter 6. For example, Equation (45) from Chapter 6 gives the relationship between space sensible heat gain, space moisture addition, supply airflow rate, and air enthalpy change from supply to exhaust conditions. Similarly, Equation (43) then relates input and output enthalpies and flow rates of mixing boxes, and Equation (36) the heating requirements at a coil to its inlet and outlet enthalpies. Equations (37) and (38) relate air mass flows, enthalpies, and moisture-removal rates for cooling-dehumidifying coils. [These particular equations must be augmented, however, with some type of model representing moisture removal and sensible cooling capability of the physical cooling coil, as discussed in Chapter 5, Equations (65) through (67).]

Since secondary systems are composed of mixing boxes, cooling coils, heating coils, and fans interconnected in various ways, mathematical models can be developed by assembling the applicable equations. For example, all mass and energy balance equations for a variable air volume terminal reheat system can be developed into an algorithm in which airflow rate, cooling coil energy rate, and reheating energy rate are calculated, given a particular required space sensible load on one or more service zones.

Models for Fans

A complete secondary system also requires a mathematical model for supply and return fans for two reasons: the required fan power must be calculated, since fan energy usage is an important factor and most, if not all, of the fan power is ultimately degraded to heat in the airstream, adding to cooling coil loads or reducing heating coil loads, depending on the fan location.

Computation of fan power is usually based on a characteristic curve, giving fraction of rated input power versus fraction of rated volume. This curve is determined principally by the method used to control air volume (see Figure 10). These curves can be determined experimentally or obtained from the manufacturer, although those shown in the figure are often accurate enough for energy analysis. Rated power can be calculated from rated volumetric flow rate, pressure rise, and efficiency as

$$\text{Fan horsepower} = \frac{Q \Delta p}{6370\ \eta_F\ \eta_M} \quad (41)$$

where

Q = air volumetric flow, cfm
Δp = fan total pressure rise, in. of water
η_F = fan efficiency
η_M = motor efficiency

Most models assume that some fraction of the fan motor power goes directly into heating (enthalpy rise) of the air as it passes through the fan. The fraction is 1.0 if the fan motor is mounted in the airstream, and 1.0 minus motor efficiency η_m if mounted outside. The increase in air enthalpy occurs immediately downstream of the fan.

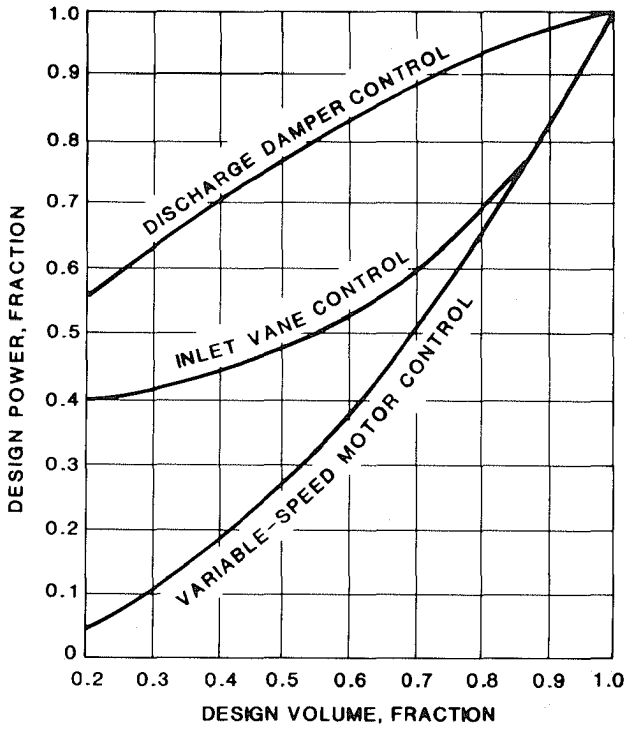

Fig. 10 Fan Power versus Volume Characteristics

Modeling of System Controls

From a mathematical viewpoint, system control devices represent equations that must be satisfied at each point during the simulation and equations that model other system components. For example, the room thermostat can be represented as a function relating heating and cooling delivery rate to space temperature, as shown in Figure 9. Similarly, cooling coil reset controls can be modeled as a relationship between outside or zone temperature and coil discharge temperature. An accurate secondary system model must ensure that all controls are properly represented and that the governing equations are satisfied at each simulation time step. This usually creates a need for iteration or, alternately, for use of values from an earlier solution point.

The controls on space temperature affect the interaction between loads calculation and secondary system simulation (see Figure 8). A realistic model might require a dead band in space temperature (Figure 9), in which no heating or cooling is called for; within this range, the true space sensible load is zero, and the true space temperature must be adjusted accordingly. If the thermostat has proportional control between zero and full capacity, the space temperature will rise in proportion to the load during cooling and fall similarly during heating. Capacity to heat or cool also varies with space temperature after the control device has reached its maximum because capacity is proportional to the *difference* between supply and space temperatures. Failure to properly model these phenomena results in overestimating required energy.

Integration of System Models

To demonstrate the approach to system modeling, a variable air volume (VAV) system serving three zones is shown in Figure 11. For simplicity, the following assumptions are made: (1) the space temperatures, sensible loads, and latent loads have been previously determined by the heat balance method; (2) the loads are within the capacities of the respective heating and/or cooling equipment; (3) the fan is a variable volume unit with the fraction of nominal

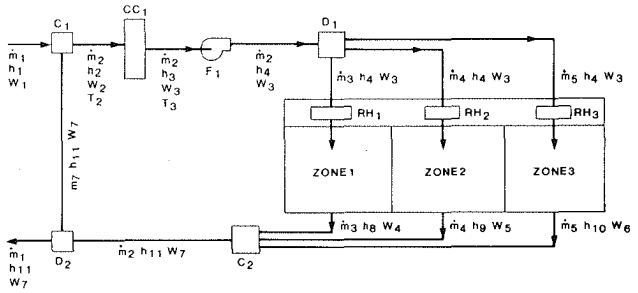

Fig. 11 Schematic of Variable Air Volume System Serving Three Zones

power expressible by a second-order polynomial in fraction of nominal volume; (4) the cooling coil discharge temperature is scheduled linearly with the temperature of the warmest zone; and (5) the outside air quantity is fixed.

In this example, the physical quantities used are mass flow rate, enthalpy, and absolute humidity. Temperature, volumetric flow rate, and other measures of air moisture are viewed as auxiliary quantities that can be computed using the psychrometric relationships from Chapter 6. However, many computer programs are based on volume flow rate, temperature, and absolute humidity, treating enthalpy and mass flow rate as auxiliary variables. The latter approach uses more familiar quantities, but tends to make the conservation equations more complicated. For example, at a mixing box, mass, not volume, is conserved. However, if density changes and the effect of moisture on enthalpy are ignored, the conservation equations can be written in terms of volumetric flow and temperature. Many analysts take this approach and accept the small attendant errors.

The schematic diagram is first labeled for mass flow rates, enthalpies, humidity ratios, and temperatures. In doing this, the number of unique variables can be minimized by observing that enthalpy and humidity do not change across a distributor, humidity does not change across the fan, and so on. Heat *added* to the space is positive and heat *removed* from the space is negative. A data table, showing the quantities assumed, is helpful.

These preliminary steps are followed by constructing a calculation sequence or algorithm that shows exactly how the input data are transformed into the output data. Usually, the best place to start is at a point where the most information is available, in this case, at the outside air mixing box M_1. Unknown quantities are simply assumed. Mass, energy, and moisture balances are then used to calculate subsequent quantities around the flow circuit. Occasionally one or more quantities must be assumed to proceed; then the calculations are repeated until the calculated quantities agree with the assumed quantities.

Algorithm for VAV System Simulation

1. Assume m_7, W_7, and h_{11}.
2. Compute $m_2 = m_1 + m_7$
   $h_2 = (m_1 h_1 + m_7 h_{11})/m_2$
   $W_2 = (m_1 W_1 + m_7 W_7)/m_2$
3. Compute T_2 using Equation (29), Chapter 6.
4. Determine cooling coil leaving conditions:
   (a) Find maximum zone temperature.
   (b) From cooling coil control schedule, determine desired leaving temperature T_{cc}.
   (c) If $T_{cc} < T_2$
   Then: set $T_3 = T_{cc}$
   Else: set $T_3 = T_2$
   (d) Compute h_3 and W_3, using h_2, W_2, T_3, and a suitable model for coil moisture removal, with Equation (29), Chapter 6.

5. Compute fan leaving conditions h_4.
   (a) Fan power: $P_F = P_{Fn} F_F(m_2/m_{2n})$,
where n represents nominal quantities, and F_F is the fan characteristic, *e.g.*, Figure 10. Note that computing volume ratio would be more accurate.
   (b) Leaving enthalpy: $h_4 = h_3 + F_{Fa}P_F/m_2$,
where F_{Fa} is the fraction of fan power entering the airstream.

6. Determine air mass flow rate, supply enthalpy, return humidity ratio, and reheat coil energy rate for each zone. Repeat (a) through (f) for each zone:
   (a) Assume zone mass flow m_z (minimum or last value)
   (b) Compute zone humidity $W_z = W_3 + Q_{zl}/(m_z h_{zwv})$, where h_{zwv} is the enthalpy of vaporization at temperature T_z
   (c) Compute zone enthalpy h_z from Equation (29), Chapter 6
   (d) If $Q_{zs} + Q_{zl} \ll \_\_ m_{z,\,min}(h_z - h_4)$
   Then: $m_2 = m_{z,\,min}$
   $h_{z,\,sup} = h_z - (Q_{zs} + Q_{zl})/m_z$
   Else: $h_{z,\,sup} = h_4$
   $m_z = (Q_{zs} + Q_{zl})/(h_z - h_{z,\,sup})$
   (e) Compute reheat required
   $Q_{RH,\,z} = m_z (h_{z,\,sup} - h_4)$
   (f) If m_z differs significantly from that used in 6a, repeat from 6b

7. Compute
$$m_2 = m_3 + m_4 + m_5$$
$$h_{11} = (m_3h_8 + m_4h_9 + m_5h_{10})/m_2$$
$$W_7 = (m_3W_4 + m_4W_5 + m_5W_6)/m_2$$

8. Compute $m_7 = m_2 - m_1$

9. If any of the values m_7, W_9, h_{11} is significantly different from values assumed in step 1, repeat all calculations from steps 2 through 8.

10. Compute cooling coil load

$$Q_{cc} = m_2 [(h_2 - h_3) - (W_2 - W_3) h_{w2}]$$

where h_{wz} is the enthalpy of *liquid* water at temperature of leaving air.

This basic algorithm for simulation of a VAV system might be used in conjunction with a heat balance-type load calculation. For a weighting factor approach, it would have to be modified to allow variation in the zone temperatures and consequently in readjustment of zone loads. It should also be enhanced to allow for possible limits on reheat temperature and/or cooling coil limits, zone humidity limits, outside air control schemes (economizers), and/or heat-recovery devices, zone exhaust, return air fan, heat gain in the return air path because of lights, the presence of baseboard-type heaters, and more realistic control profiles. Most current building energy programs incorporate these and other features as user options, as well as algorithms for other types of systems.

SIMULATING PRIMARY ENERGY CONVERSION SYSTEMS

Primary energy conversion equipment (plant equipment) is simulated to calculate the energy used and associated cost required to meet the heating, cooling, and/or electrical loads of a building. Manufacturers specify the performance of equipment for the design operating conditions. Temperatures and flow rates other than the design values affect both the COP and capacity of the chiller. Also, operating the chiller at less than full capacity affects the COP. Some parameters can affect the performance of the machine significantly on an hour-by-hour basis; others may have very small effects. Modeling the equipment accurately requires hourly determination of the important parameters.

Performance Correction Curves

Off-design performance data are much harder to obtain; in some cases, the manufacturer does not know the off-design performance. For this reason, equipment simulation algorithms should include general correction functions to modify the design data for off-design performance. If the off-design performance is known, the algorithm should allow this to override the general correction functions.

The functions can take any appropriate form, including polynomials, exponentials, Fourier series, and so forth. Most computer algorithms use polynomials, usually third order or less. The necessary degree of the polynomial depends on the behavior of the equipment. It is also possible to use tables of data; however, this method may require excessive data input and computer memory.

Boiler Algorithms

The hourly performance of a boiler depends on boiler load, boiler characteristics and, to a lesser extent, on ambient air temperature. Because the ambient temperature dependence is small (usually $< \pm 2\%$), it is often ignored.

Electric boilers. Assuming the electric resistance heating losses of the loads supplying the boiler are negligible, the only losses affecting its efficiency are the radiative and/or conductive losses through the shell. If the ambient temperature is relatively constant, the loss through the shell can be considered constant, and the electrical consumption is

$$E = \text{Load} + \text{Loss} \tag{42}$$

If the boiler experiences wide swings in environmental temperature, the loss term must take this into account.

Fossil fuel boilers. Fossil fuel-fired boilers are more complex to model because the combustion efficiency usually varies with the load. If the combustion efficiency is constant, the electric boiler Equation (42) can be used. Nonconstant combustion efficiency requires one of the following models:

Fuel consumption calculated as a function of efficiency (heat energy output and/or fuel energy input). Load divided by the capacity defines the part-load ratio

$$\text{PLR} = \text{Load/Capacity} \tag{43}$$

The efficiency for part-load ratios less than 1.0 (PLR = 1.0 corresponds to the design output) is the design efficiency corrected by a function of the part-load ratio

$$\text{Eff} = \text{Eff}_{design} f(\text{PLR}) \tag{44}$$

The fuel consumed is then

$$F = \text{Load/Eff} \tag{45}$$

Since the efficiency at PLR = 0 must be zero, the correction function must have a form similar to curve 1 in Figure 12.

Some boilers with dampers or other means of maintaining an almost constant air/fuel ratio for varying loads may have an almost constant efficiency correction curve until very low loads are encountered. At very low loads, the efficiency curve will bend sharply to zero (curve 2 in Figure 12). This kind of curve cannot be modeled accurately with a low-order polynomial. Therefore, the form presented next should be used instead.

Fuel consumption calculated as fraction of full-load fuel consumption. This model takes the form

$$F = F_{design} f(\text{PLR}) \tag{46}$$

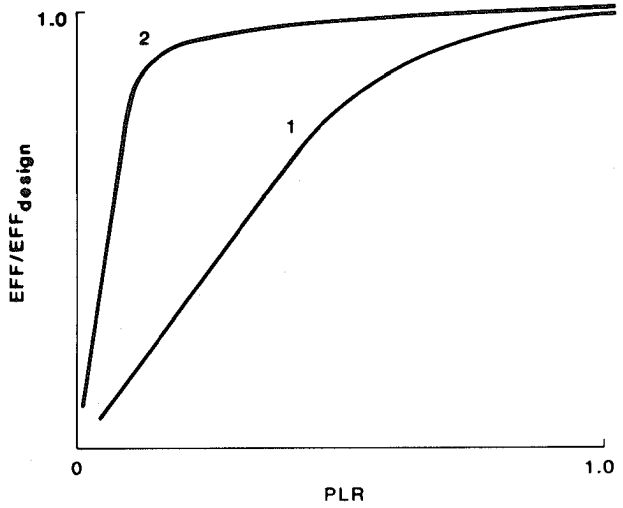

Fig. 12 Efficiency Model for Fossil Fuel Boiler

Figure 13 indicates the possible shapes of the correction factor. Curve 1 is for a boiler with a constant efficiency (not possible in reality); curve 2 is for a boiler that is most efficient toward the middle of its operating range; and curve 3 is for a boiler that is most efficient at full load. For many boilers, the function f (PLR) is consistent and can be approximated easily with a low-order polynomial. For this reason, this model, rather than the efficiency model described earlier, should be used.

If a fossil boiler has draft fans, fuel pumps, etc., the electrical consumption can be modeled either as a constant (no dependence on load) or as a variable (changes with the load). If the electrical consumption varies with the load, it can be modeled in a fashion analogous to Equation (44).

Chillers

The capacity of a chiller usually depends on the condenser and chilled water temperatures. The design capacity is usually rated at a chilled water temperature of 44 °F and an entering condenser water temperature of 85 °F. Water flow rates are usually 2.5 gpm/ton and 3.0 gpm/ton, respectively. For entering condenser water temperatures less than 85 °F and for chilled water temperatures greater than 44 °F, the capacity is greater than the design capacity. The converse is also true. The hourly operating capacity must be calculated to determine the number of chiller units needed to meet the cooling load (in multiple-unit installations), and to calculate the space conditions or cooling overloads.

Assuming the water flow rates remain constant, the capacity adjustment factor can be expressed as a biquadratic polynomial function of the condenser and chilled water temperatures. The hourly available capacity is then

$$C_{avail} = C_{nom} f\ (t_{cold}, t_{cond}) \qquad (47)$$

The power consumption of a chiller also depends on the chilled and condenser water temperatures. The load also affects the performance. Dependence on load can be modeled by either of the methods described for boilers, although the second method is used here for f_1. The dependence on temperatures can be modeled as a biquadratic function or as two quadratic functions. A biquadratic function f_2 is used here. The power consumed is expressed as

$$P = P_{design} f_1\ (t_{cold}, t_{cond}) f_2\ (\text{PLR}) \qquad (48)$$

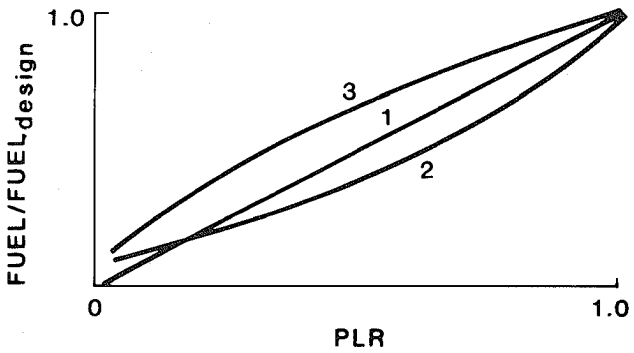

Fig. 13 Fuel Consumption Model for Fossil Fuel Boiler

When modeling an absorption chiller, an equation of the same form as Equation (48) can be used to calculate thermal energy consumption. An absorption machine's electrical consumption is usually modeled as constant, although variable consumption can be modeled by using an equation of the same form as Equation (46).

When simulating a double-bundle chiller operating in the heat-recovery mode, the capacity and energy consumption are determined by the leaving condenser water temperature rather than the entering condenser water temperature. During times of heat recovery operation, the function f_1 in Equation (48) should be replaced by a function that takes the (constant) higher leaving condenser water temperature into account.

When simulating chillers with air-cooled condensers, Equation (48) can still be used to calculate the energy consumption; however, function f_1 should take the ambient air temperature into account rather than the entering condenser water temperature.

Modeling False Loading and Cycling Effects in Chillers

If a compression chiller uses hot gas bypass or some other means to maintain an adequate refrigerant flow through the compressor during low load conditions, the compressor operates under a load larger than the external load on the machine. This additional load, called a false load, causes the compressor to consume as much electricity as if the entire load were external to the chiller. The *minimum unloading ratio* (MUR) is the smallest part-load ratio at which the compressor can operate without false loading. When the chiller is operating at less load, the compressor is operating at MUR. PLR in Equation (48) should be replaced by MUR during periods of false loading to simulate this effect.

If a chiller cycles on and off at low loads with no false loading, the function f_2 in Equation (48) usually includes this behavior, so that f_2 is then valid for

$$0 \leq \text{PLR} \leq 1.0$$

However, if the chiller first false loads and then starts cycling on and off as the load decreases, the function f_2 will not be smooth and may need to be divided into discrete intervals of PLR. Another way to approximate this behavior without breaking the range of PLR into discrete intervals is to assume that the energy consumed while cycling is proportional to the fraction of the hour the machine is cycled on.

Cooling Towers

A cooling tower is simulated to calculate the leaving water temperature for use in the chiller algorithms and to calculate the electrical consumption of tower fans. The performance of a tower depends on the wet-bulb temperature, the temperature drop of the water flowing through the tower (the range), and how closely the water temperature approaches the wet-bulb temperature (the

approach). Performance charts relating the wet-bulb, range, and approach to a fourth quantity defined as the *rating factor* are available. The rating factor, when coupled with the tower water flow rate, can be used to determine the number of tower cells and airflow rates needed to produce the desired exit water temperature. Additionally, the same set of relations can be used to calculate the floating temperature that occurs when all cells running at the maximum airflow rate cannot produce the desired exit temperature.

OVERALL MODELING STRATEGIES

In developing a simulation model for building energy prediction, two basic issues must be considered—modeling of components or subsystems, and the overall modeling strategy. Component or subsystem models are merely mathematical equations relating the physical variable that must be continuously satisfied. Overall modeling strategy refers to the *sequence* and *procedures* used to solve these equations, which have important implications, including accuracy of the results and computer resources required to achieve the results. These are discussed briefly in this section.

Virtually all building energy programs in use today employ the same overall modeling strategy. In this strategy, the loads model is executed for every space for every hour of the simulation period. This is followed by employing the systems model for every secondary system, one at a time, for every hour of the simulation. Finally, the plant simulation model is executed again for the entire period. Each sequential execution processes the *fixed* output of the preceding step.

Because of this loads-systems-plants sequence, certain phenomena cannot be modeled precisely. For example, if the heat balance method for computing loads is used, and some component in the system simulation model cannot meet the load, the program can only report the current load. In actuality, the space temperature should readjust until the load matches the equipment capacity, but this cannot be modeled since the loads have been precalculated and fixed. If the weighting factor method is used for loads, this problem is partially overcome, since loads are continually readjusted during the system simulation execution. However, the weighting factor technique is based on linear mathematics, and wide departures of room temperatures from those used during the loads program execution can introduce errors.

A similar problem arises in plant simulation. For example, in an actual building, as the load on the central plant varies, so does the supply chilled water temperature, which in turn affects the capacity of the secondary system equipment. In the extreme case, when the central plant becomes overloaded, space temperatures should rise to reduce the load. However, in modeling strategies used in most current programs, this cannot occur; thus, only the overload condition can be reported. These are some of the penalties associated with decoupling of the loads, systems, and plants models.

An alternative overall modeling strategy, in which all calculations are carried out at each time step, is conceivable. Here the loads, systems, and plant models are viewed together as a single set of equations to be solved simultaneously at each point in time. The unmet loads and imbalances discussed earlier cannot arise; conditions at the plant are immediately reflected to the secondary system and then to the load model, forcing them to readjust to the instantaneous conditions throughout the building. The results of this modeling strategy are superior to those currently available, although the magnitude and importance of the improvement are difficult to judge.

The principal disadvantage of the alternative approach, and the reason that it is not widely used, is that it is more demanding of computing resources. For example, memory requirements tend to be somewhat proportional to the number of surfaces used to model the individual spaces in the building. For example, if 25 spaces are modeled with the alternative strategy, 10 to 15 times as much memory is required. Also, solution time tends to increase at least linearly with the number of simultaneous equations to be solved, *i.e.*, it takes longer to solve 10 spaces together than to solve them one at a time. Conversely, if these difficulties could be overcome, perhaps by the use of more efficient algorithms in the models themselves, the approach might be feasible.

Another issue related to overall modeling strategy, and one that also affects component models, is the *timewise resolution* sought from the model. Practically all models in use today use one hour as the time-step, which precludes any information on phenomena occurring in a shorter time span. Miller (1980) found that the dynamics of control of components may have at least minor effects on predicted energy use.

SMALL TIME-STEP SIMULATION

The nature of a building's design, mechanical system, or control strategy affects the level of simulation needed. For most analyses, an hour-by-hour, quasi-steady state simulation is adequate. However, a closed loop control or real-time performance testing and evaluation of controls may require advanced simulation techniques that involve small time steps. Closed-loop control regulates the output of a "plant" or physical process by comparing it with the desired output response. The difference (error) is then used to control the process close to a predefined (although possible time-varying) set point.

Simulations can model the performance of energy-saving application programs or algorithms for Energy Management and Control Systems (ECMS). The application algorithm then controls the modeled system, and any problems can be corrected before the algorithm is implemented on a real system. The simulated system can be part of a main program that calls the application algorithm and runs at computer speed, or it may reside on a separate computer and run in "real" time. The latter process is often called *emulation* rather than simulation.

A simulation that considers system dynamics is often required to evaluate sophisticated control strategies. If local loop control dynamics are unlikely to significantly impact the energy consumed, a minute-by-minute simulation is probably sufficient. If local loop control dynamics are important, a second-by-second simulation may be needed. Simulation programs reported by Kelly *et al.* (1984), Shavit (1977), Hacker *et al.* (1984, 1985), and Benton *et al.* (1982) have the ability, to varying degrees, of modeling dynamic building control strategies and the interactions between the building shell, the HVAC system, and the controls.

Performance Testing and Evaluation

The control algorithms provided by most EMCS manufacturers or suppliers are usually proprietary. The source code may be available for purchase on a site-specific basis, but it usually does not help in evaluating how well such algorithms actually work or how much energy they save. A control algorithm can be evaluated only by:

- Gathering data on actual buildings controlled by the EMCS
- Testing an EMCS connected to actual HVAC equipment in a laboratory
- Using a building/HVAC system emulator

The emulator, the only practical alternative for testing, consists of a special computer connected to the sensor input and command outputs of an EMCS. No actual HVAC equipment or building is used. Instead, a computer program simulates the response of building systems (including the equipment, building space, and building envelope) to the control strategies and commands imple-

mented by the EMCS. Thus the EMCS can be tested with any type of building, HVAC system, and/or climatic conditions that the emulator can simulate. The emulator keeps track of the energy consumed by the hypothetical building, so that a quantitative measure of the performance of the EMCS system and the supervisory control algorithm is obtained. The results can then be compared with those obtained with different EMCS systems or with a standard set of EMCS application algorithms. May (1985) and Wise (1984) describe two prototypes that demonstrate EMCS testing with an emulator.

SOLAR ENERGY ESTIMATES

Solar heating and/or cooling can be incorporated into buildings through active or passive systems. Active solar systems use either liquid or air as the collector fluid. A complete system includes solar collectors, energy storage devices, and pumps or fans for transferring energy to storage or to the load. The load can be space cooling, heating, or hot water. Although it is technically possible to construct a solar heating and cooling system to supply 100% of the design load, that system would be oversized for seasonal operation and, generally, uneconomical. The size of the solar system, and thus its ability to meet the load, is determined by life-cycle cost analysis that weighs the cost of energy saved against the amortized solar system cost.

Active solar energy systems have been combined with heat pumps for water and/or space heating. The most economical arrangement in residential heating is a solar system in parallel with a heat pump, which supplies auxiliary energy when the solar source is not available. For domestic water systems requiring high water temperatures, a heat pump placed in series with the solar storage tank may be advantageous. Freeman *et al.* (1979) and Morehouse and Hughes (1979) present information on performance and estimated energy savings for solar heat pump systems.

Passive hybrid solar systems incorporate solar collection, storage, and distribution into the architectural design of the building and make minimal or no use of fans to deliver the collected energy to the structure. The concepts involved in passive hybrid solar heating, cooling, and lighting include the building envelope and its orientation, thermal storage mass, and window configuration and design. DOE (1980), LBL (1981), Mazria (1979), and ASHRAE (1984b) give estimates of energy savings resulting from the application of passive solar design concepts. Hybrid systems combine elements of both active and passive systems.

Methods used to determine solar heating and/or cooling energy requirements for both active and passive/hybrid systems are described by Feldman and Merriam (1979) and Hunn *et al.* (1987). Descriptions of public and private domain methods are included. An overview of the simulation techniques suitable for active heating and cooling systems analysis, and for passive/hybrid heating, cooling, and lighting analysis follows.

SIMPLIFIED METHODS

Simplified analysis methods have advantages of computational speed, low cost, rapid turnaround (especially important during iterative design phases), and the ability to be used by persons with little technical experience. Disadvantages include limited flexibility for design optimization, lack of control over assumptions, and a limited selection of systems that can be analyzed. Thus, if the system application, configuration, or load characteristics under consideration are significantly nonstandard, a detailed computer simulation may be required to achieve accurate results. This section describes the *f*-Chart method for active solar heating and the Solar Load Ratio method for passive solar heating (see Dickinson and Cheremisinoff (1980), Lunde (1980), and Klein and Beckman (1979).

ACTIVE HEATING/COOLING SYSTEMS

Beckman *et al.* (1977) developed the *f*-Chart method using an hourly simulation program (Klein *et al.* 1976) to evaluate space heating and service water heating systems in many climates and conditions. The results of these analyses correlate the fraction of the heat load f met by the solar energy system. The correlations give the fraction f of the monthly heating load (for space heating and hot water) supplied by solar energy as a function of collector characteristics, heating loads, and weather. The standard error of the differences between detailed simulations in 14 locations in the United States and the *f*-Chart predictions was about 2.5%. Correlations also agree within the accuracy of measurements of long-term system performance data. Beckman *et al.* (1977, 1981), and Duffie and Beckman (1980) discuss the method in detail.

The *f*-Chart method requires the following data:

- Monthly average daily radiation on a horizontal surface
- Monthly average ambient temperatures
- Collector thermal performance curve slope and intercept from standard collector tests, *i.e.*, $F_R U_L$ and $F_R(\tau\alpha)_n$ (see ASHRAE *Standard* 93 and Chapter 34, 1992 ASHRAE *Handbook—Systems and Equipment*)
- Monthly space and water heating loads

Standard Systems

The *f*-Chart assumes several standard systems and applies only to these liquid configurations. The standard *liquid system* uses water, an antifreeze solution, or air as the heat transfer fluid in the collector loop and water as the storage medium (Figure 14). Energy is stored in the form of sensible heat in a water tank. A water-to-air heat exchanger transfers heat from the storage tank to the building. A liquid-to-liquid heat exchanger transfers energy from the main storage tank to a domestic hot water preheat tank, which in turn supplies solar heated water to a conventional water heater. A conventional furnace or heat pump is used to meet the space heating load when the energy in the storage tank is depleted.

Figure 15 shows the assumed configuration for a solar *air heating system* with a pebble-bed storage unit. Energy for domestic hot water is provided by heat exchange from the air leaving the collector to a domestic water preheat tank as in the liquid system. The hot water is further heated, if necessary, by a conventional water heater. During summer operation, a seasonal, manually operated storage bypass damper is used to avoid heat loss from the hot bed into the building.

The standard solar *domestic water heating system* collector heats either air or liquid. Collected energy is transferred by a heat exchanger to a domestic water preheat tank that supplies solar-heated water to a convectional water heater. The water is further heated to the desired temperature by conventional fuel if necessary.

f-Chart Method

Computer simulations correlate dimensionless variables and the long-term performance of the systems. The fraction of the monthly space and water heating loads supplied by solar energy f is empirically related to two dimensionless groups. The first dimensionless group is collector loss; the second is collector gain. These groups are defined as:

$$X = F_R U_L (F_r/F_R)(t_{ref} - \bar{t}_a)\,\Delta\theta A_c/L \qquad (49)$$

$$Y = F_R (\tau\alpha)_n (F_r/F_R)\,(\tau\alpha)/(\tau\alpha)_n\,\bar{H}_T N A_c/L \qquad (50)$$

where

A_c = area of solar collector, ft^2
F_r = collector-heat exchanger efficiency factor
F_R = collector efficiency factor
U_L = collector overall energy loss coefficient, Btu/h · ft^2 · °F
$\Delta\theta$ = total number of seconds (or hours) in month, depending on units of U_L
$\bar{t}_a$ = monthly average ambient temperature, °F
L = monthly total heating load for space heating and hot water, Btu
$\bar{H}_T$ = monthly averaged, daily radiation incident on collector surface per unit area, Btu/day · ft^2
N = number of days in month
$(\overline{\tau\alpha})$ = monthly average transmittance-absorptance product
t_{ref} = reference temperature, 212 °F

$F_R U_L$ and $F_R\,(\tau\alpha)_n$ are obtained from collector test results. The ratios F_r/F_R and $(\overline{\tau\alpha})/(\tau\alpha)_n$ are calculated using methods given by Beckman *et al.* (1977). The value of $\bar{t}_a$ is obtained from meteorological records for the month and location desired. $\bar{H}_T$ is found from the monthly average, daily radiation on a horizontal surface by the methods in Chapter 34 of the 1992 ASHRAE *Handbook—Systems and Equipment* or in Duffie and Beckman (1980). The monthly load L can be determined by any appropriate load estimating method, including analytical techniques or measurements. Values of the collector area A_c are selected for the calculations. Thus, all the terms in these equations can be determined from available information.

Transmittance of the transparent collector cover system τ and the absorptance of the collector plate α depend on the angle at which solar radiation is incident on the collector surface. Collector tests are usually carried out with the radiation incident on the collector in a nearly perpendicular direction. Thus, the value of $F_R\,(\tau\alpha)$ determined from collector tests ordinarily corresponds to the transmittance and absorptance values for radiation at normal incidence. Depending on the collector orientation and the time of year, the monthly averaged values of the transmittance and absorptance can be significantly lower. The *f*-Chart method requires a knowledge of the ratio of the monthly average to normal incidence transmittance-absorptance.

The *f*-Chart method for liquid systems is similar to that for air systems. The fraction of the monthly total heating load supplied by the solar air heating system is correlated with the dimensionless groups X and Y, as shown in Figure 16. To determine the fraction of the heating load supplied by solar energy for a month, values of X and Y are calculated for the collector and heating load in question. The value of f is determined at the intersection of X and Y on the *f*-Chart, or from the following equivalent equations.

$$\text{Air system: } f = 1.04\,Y - 0.065\,X - 0.159\,Y^2 + 0.00187\,X^2 - 0.0095\,Y^3 \qquad (51)$$

$$\text{Liquid system: } f = 1.029\,Y - 0.065\,X - 0.245\,Y^2 + 0.0018\,X^2 + 0.025\,Y^3 \qquad (52)$$

This is done for each month of the year. The solar energy contribution for the month is the product of f and the total heating load L for the month. Finally, the fraction of the annual heating load supplied by solar energy F is the sum of the monthly solar energy contributions divided by the annual load:

$$F = \Sigma f L/\Sigma L$$

Example 4. Calculating the heating performance of a residence, assume that a solar heating system is to be designed for Madison, WI, with two-cover collectors facing south, inclined 58° with respect to horizontal. The air heating collectors have the characteristics: $F_R U_L = 0.50$ Btu/h · ft^2 · °F and $F_R\,(\tau\alpha)_n = 0.49$. The total space and water heating load for January is calculated to be 34.1×10^6 Btu, and the solar radiation incident on the plane of the collector is calculated to be 1.16×10^3 Btu/day · ft^2. Determine the fraction of the load supplied by solar energy with a system having a collector area of 538.2 ft^2.

Solution: For air systems, there is no heat exchanger penalty factor and $F_r/F_R = 1$. The value of $(\overline{\tau\alpha})/(\tau\alpha)_n$ is 0.94 for a two-cover collector in January. Therefore, the values of X and Y are

$$X = (0.50\text{ Btu/h} \cdot \text{ft}^2 \cdot °\text{F})\,(212 °\text{F} - 19.4 °\text{F})\,(31\text{ days})\,(24\text{ h/day})\,(538.2\text{ ft}^2)/(3.41 \times 10^7\text{ Btu}) = 1.13$$

$$Y = (0.49)\,(1)\,(0.94)\,(1.16 \times 10^3\text{ Btu/day} \cdot \text{ft}^2)\,(31\text{ days})\,(538.2\text{ ft}^2)/(34.1 \times 10^6\text{ Btu}) = 0.26$$

Then the fraction of the energy f supplied for January from Figure 16 is 0.19. The total solar energy supplied by this system in January is

$$fL = 0.19 \times 34.1 \text{ MMBtu} = 6.4 \times 10^6 \text{ Btu}$$

The annual system performance is obtained by summing the energy quantities for all months. The result is that 37% of the annual load is supplied by solar energy.

The collector heat removal factor F_R that appears in X and Y is a function of the collector fluid flow rate. Because of the higher cost of power for flowing fluid through air collectors than through liquid collectors, the capacitance rate used in air heaters is ordinarily much lower than that in liquid heaters. As a result, air heaters generally have a lower value of F_R. Values of F_R corresponding to the expected airflow rate in the collector must be used in calculating X and Y.

An increase in airflow rate tends to improve collector performance by increasing F_R, but it tends to decrease system performance by reducing the degree of thermal stratification in the pebble bed (or water storage tank). The f-Chart for air systems is based on a collector airflow rate of 2 scfm/ft^2 of collector area. The performance of systems with different collector airflow rates can be estimated by using the appropriate values of F_R in both X and Y. A further modification to the value of X is required to account for the change in degree of stratification in the pebble bed.

The performance of air systems is less sensitive to storage capacity than that of liquid systems for two reasons: (1) air systems can operate with air delivered directly to the building in which the storage component is not used, and (2) pebble beds are highly stratified and additional capacity is effectively added to the cold end of the bed, which is seldom heated and cooled to the same extent as the hot end. The f-Chart for air systems is for a nominal storage capacity. The performance of systems with other storage capacities can be determined by modifying the dimensionless group X as described in Beckman *et al.* (1977).

With modification, f-Charts can be used to estimate the performance of a solar water heating system operating in the range of 120 to 160°F. The main water supply temperature, and the minimum acceptable hot water temperature (*i.e.*, desired delivery temperature) both affect the performance of solar water heating systems. The dimensionless group X, which is related to collector energy losses, can be redefined to include these effects. If monthly values of X are multiplied by a correction factor, the f-Chart for liquid-based solar space and water heating systems can be used to estimate monthly values of f for water heating systems. Experiments and analysis show that the load profile for a well-designed system has little effect on long-term performance. Although the f-Chart was originally developed for two-tank systems, it may be applied to single- and double-tank domestic hot water systems with and without collector tank heat exchangers.

For industrial process heating, absorption air conditioning, or other processes for which the delivery temperature is outside the normal f-Chart range, modified f-Charts are applicable (Klein *et al.* 1976). The concept underlying these charts is that of solar usability, which is the fraction of the total solar energy that is useful in the given process. This fraction depends on the required delivery temperature as well as collector characteristics and solar radiation. The procedure allows the energy delivered to be calculated in a manner similiar to that for f-Charts. An example of the application of this method to solar-assisted heat pumps is presented in Svard *et al.* (1981).

Other Active System Methods

The *relative areas method*, based on correlations of the f-Chart method, predicts annual rather than monthly active heating system performance (Barley and Winn 1978). An hourly simulation program has been used to develop the *monthly solar-load ratio* (SLR) *method*, another simplified procedure for residential systems (Dickinson and Cheremisinoff 1980). Based on hour-by-hour simulations, a method was devised to estimate system performance based on monthly values of horizontal solar radiation and heating degree days. This SLR method has also been extended to nonresidential buildings for a range of design water temperatures (Dickinson and Cheremisinoff 1980, Schnurr *et al.* 1981).

Passive Heating Systems

The most widely accepted simplified passive space heating design tool is the solar-load ratio method (DOE 1980, 1982, ASHRAE 1984b). It can be applied manually, although like the f-Chart, it is available on microcomputer software. The SLR method for passive systems is based on correlating results of multiple hour-by-hour computer simulations, the algorithms of which have been validated against test cell data for generic passive heating system types: direct gain, thermal storage wall, and attached sunspace. Monthly and annual performance, as expressed by the auxiliary heating requirement, is predicted by this method. The method applies to single-zone, envelope-dominated buildings. A simplified, annual-basis distillation of SLR results, the *load collector ratio* (LCR) *method*, and several simple-to-use rules have grown out of the SLR method. Several hand-held calculator and microcomputer programs have been written using the methodology (Nordham 1981).

The SLR method uses a single dimensionless correlating parameter (SLR), which Balcomb *et al.* (1982) define as a particular ratio of solar energy gains to building heating load.

$$\text{SLR} = \frac{\text{Solar energy absorbed}}{\text{Building heating load}} \tag{53}$$

A correlation period of 1 month is used; thus the quantities in the SLR are calculated for a 1-month period.

The parameter that is correlated to the SLR, the *solar savings fraction* (SSF), is defined as

$$\text{SSF} = 1 - \frac{\text{Auxiliary heat}}{\text{Net reference load}} \tag{54}$$

The SSF measures energy savings expected from the passive solar building, relative to a reference nonpassive solar building.

In this equation, the net reference load is equal to the degree-day load of the nonsolar elements of the building as

$$\text{Net reference load} = (\text{NLC})(\text{DD}) \tag{55}$$

where NLC is the net load coefficient. This term is a modified UA coefficient computed by leaving out the solar elements of the building. The nominal units are Btu/°F·day. The quantity DD is the degree-days computed for an appropriate base temperature. A building energy analysis based on the SLR correlations begins with a calculation of the monthly SSF values. The monthly auxiliary heating requirements are then calculated by

$$\text{Auxiliary heat} = (\text{NLC})\,(\text{DD})\,(1 - \text{SSF}) \tag{56}$$

The annual auxiliary heat is the sum of the monthly values.

By definition, SSF is the fraction of the degree-day load of the nonsolar portions of the building met by the solar element. If the solar elements of the building (south-facing walls and window) were replaced by other elements so that the net annual flow of heat through these elements was zero, the annual heat consumption of the building would be the net reference load. The savings achieved by the solar elements would therefore be the net reference load minus the auxiliary heat, or

$$\text{Solar savings} = (\text{NLC})\,(\text{DD})\,(\text{SSF}) \tag{57}$$

Although simple, in many situations and climates, Equation (57) is only approximately true because a normal solar-facing wall, with a normal complement of opaque walls and windows, has a near zero effect over the entire heating season. In any case, the auxiliary heat estimate is the primary result and does not depend on this assumption.

The hour-by-hour simulations used as the basis for the SLR correlations are done with a detailed model of the building in which all the design parameters are specified. The only parameter that remains a variable is the solar collector area expressed as the load collector ratio (LCR)

$$\text{LCR} = \frac{\text{Net load coefficient}}{\text{Projected collector area}} \tag{58}$$

Performance variations are estimated from the correlations, which allow the user to account directly for thermostat set point, internal heat generation, glazing orientation, and configuration, shading, and other solar radiation modifiers. Major solar system characteristics are accounted for by selecting one of 94 reference designs. Other design parameters, such as thermal storage thickness and conductivity, and the spacing between glazings, are included in a series of sensitivity calculations obtained using the hour-by-hour simulations. These results are generally presented in graphic form so that the designer can see the effect of changing a particular design parameter.

Solar radiation correlations for the collector area have been determined using hour-by-hour simulations and Typical Meteorological Year weather data. These correlations are expressed as ratios of incident-to-horizontal radiation, transmitted-to-incident, and absorbed-to-transmitted, as a function of the latitude minus mid-month solar declination and the atmospheric clearness index K_T.

The performance predictions of the SLR method have been compared to predictions made by the detailed hour-by-hour simulations for a variety of climates in the United States. The standard error in the prediction of the annual SSF, compared to the hour-by-hour simulation, is typically 2 to 4%.

An annual solar savings fraction calculation involves summing the results of 12 monthly calculations. For a particular city, the resulting SSF depends only on LCR (the ratio of the net load coefficient to projected collector area), the system type, and the temperature base used in calculating degree days. Thus, tables that relate SSF to LCR for the various systems and for various degree-day base temperatures may be generated for a particular city. Such tables are easier for hand analysis than are the SLR correlations.

Annual SSF versus LCR tables have been developed for 209 locations in the United States and 14 cities in southern Canada for 94 reference designs and 12 base temperatures (ASHRAE 1984).

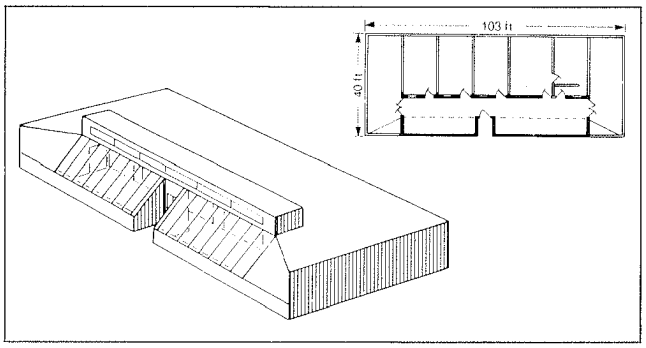

Fig. 17 Floor Plan and Perspective Drawing for Commercial Building in Example 5

Example 5. Consider a small office building located in Denver, CO, with 3000 ft^2 of usable space and a sunspace entry foyer that faces due south; the projected collector area A_p is 420 ft^2. A sketch and preliminary plan are shown in Figure 17. Distribution of solar heat to the offices is primarily by convection through the doorways from the sunspace. The principle thermal mass is in the common wall that separates the sunspace from the offices and in the sunspace floor. This example is abstracted from the detailed version given in Balcomb *et al.* (1982). Even though lighting and cooling are likely to have the greatest energy costs for this building, heating is a significant energy item and should be addressed by a design that integrates passive solar heating, cooling, and lighting strategies.

Solution: Calculations of the *net load coefficient* (NLC) are shown in Table 7.

$$\text{NLC} = 24 \times 525 = 12{,}600 \text{ Btu/°F·day}$$

and the total load coefficient (TLC) includes the solar aperture

$$\text{TLC} = 24 \times 676 = 16{,}294 \text{ Btu/°F·day}$$

The load collector ratio (LCR) is

$$\text{LCR} = \text{NLC}/A_p$$
$$= 12{,}600/420 = 30 \text{ Btu/ft}^2\text{·°F·day}$$

Suppose the daily internal heat is 130,000 Btu/day, and the average thermostat setting is 68 °F. Then

$$T_{base} = 68 - 130{,}000/16{,}294 = 60\,°\text{F}$$

(Note that solar gains to the space are not included in the internal gain term as they customarily are for nonsolar buildings.)

In this example, the solar system is type SSDI, defined in ASHRAE (1984) and Balcomb *et al.* (1982). It is a semiclosed sunspace with a 12-in. masonry common wall between it and the heated space (offices). The aperture is double-glazed, with a 50° tilt and no night insulation. To achieve a projected area of 420 ft^2, a sloped glazed area of 420/sin 50° = 548 ft^2 is required.

The SLR correlation for solar system type SSDI is shown in Figure 18. Values of the absorbed solar energy (S) and heating degree-days (DD) to base temperature 60 °F are determined monthly. For S, the solar radiation correlation presented in ASHRAE (1984) for tabulated Denver, CO, weather data are used. For January, the horizontal surface incident radiation is 840 Btu/ft^2·day. The 60 °F base degree-days are 933. Using the tabulated incident-to-absorbed coefficients found in ASHRAE (1984), S = 43,681 Btu/ft^2. Thus S/DD = 46.8 Btu/ft^2·°F·day. From Figure 19 at an LCR = 30 Btu/ft^2·°F·day, the SSF = 0.51. Therefore, for January

$$\text{Net reference load} = (933)(12{,}600) = 11.76 \times 10^6 \text{ Btu}$$
$$\text{Solar savings} = (11.76 \times 10^6)(0.51) = 6.00 \times 10^6 \text{ Btu}$$
$$\text{Auxiliary heat} = (11.76 \times 10^6) - (6.00 \times 10^6) = 5.76 \times 10^6 \text{ Btu}$$

Repeating this calculation for each month and adding the results for the year yields an annual auxiliary heat of 19.94 × 10^6 Btu.

Table 7 Estimated Heat Load Coefficients for Example Building

	Area A, ft^2	U-Value, Btu/h/ft^2·°F	UA, Btu/h·°F
Opaque wall	2000	0.04	80
Ceiling	3000	0.03	90
Floor (over crawl space)	3000	0.04	120
Windows (E, W, N)	100	0.55	55
		Subtotal	345
Infiltration			180
		Subtotal	525
Sunspace (treated as unheated space			151
		Total	676

ASHRAE procedures are approximated with V = volume, ft^3; c = heat capacity of Denver air, Btu/ft^3·°F; ACH = air changes/h; equivalent UA for infiltration = VcACH. In this case, V = 24,000 ft^3, c = 0.015 Btu/ft^3·°F, and ACH = 0.5.

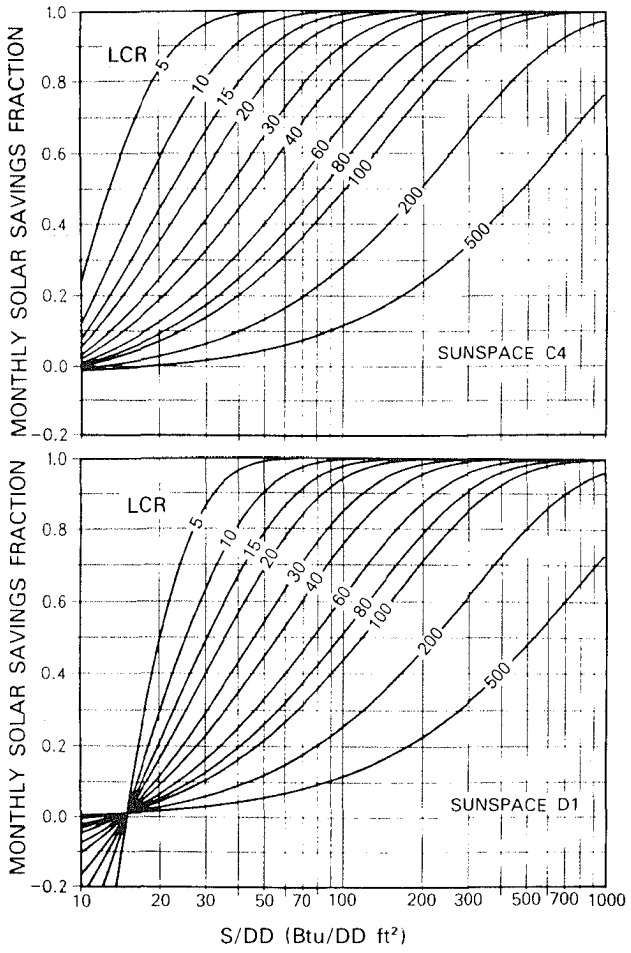

Fig. 18 Monthly SSF versus Monthly S/DD for Various LCR Values

Other Passive Heating System Methods

The concept of usability has been applied to passive buildings. In this approach, the energy requirements of a zero- and infinite-capacity building are calculated. The amount of solar energy that enters the building and exceeds the instantaneous load of the zero-capacity building is then calculated. This excess energy must be dumped in the zero-capacity building, but it can be stored to offset heating loads in a finite-capacity building. Methods are provided to interpolate between the zero- and infinite-capacity limits for finite-capacity buildings. Equations and graphs for direct gain and collector-storage wall systems are given in Monsen *et al.* (1981, 1982).

PASSIVE/HYBRID COOLING SYSTEMS

Passive hybrid cooling systems use natural environmental conditions to cool the conditioned space. Mechanical power only transports air throughout the building; it does not directly cool the air, such as in a conventional air-conditioning system. In this section, cooling by mechanically induced ventilation, natural ventilation, increased air motion, direct and indirect evaporative coolers, radiative heat transfer, and the reduction of lighting loads through daylighting are discussed.

Ventilative Cooling

A building's occupants can be cooled directly by ventilation (physiological cooling) or indirectly by reducing the mean radiant temperature of the building surfaces to which they are exposed (structural cooling). Physiological cooling can be accomplished by (1) the exchange of interior air with exterior air (air exchange method), *e.g.*, opening windows, thereby removing heat and moisture, and (2) direct cooling of occupants by air motion across the body (air motion method), thereby increasing convective and evaporative cooling. The latter can be called task cooling in that the occupant is cooled locally. Both physiological and structural cooling offer the potential for significant energy savings to the extent that they can be substituted for mechanical cooling. These methods use ambient air as a natural cooling sink and rely on either natural convection or forced convection to move the air through the building.

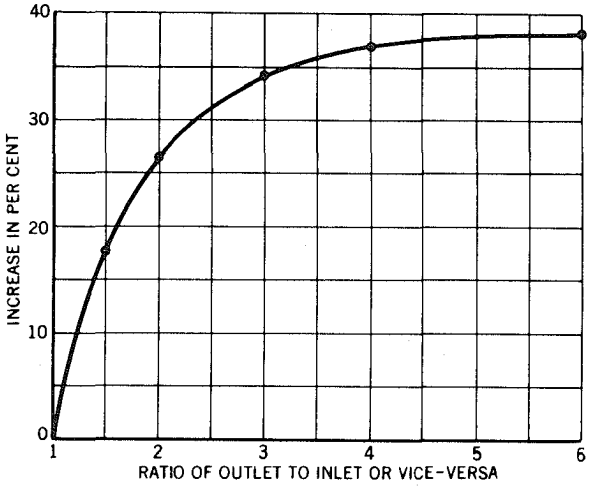

Fig. 19 Increase in Flow Caused by Excess of One Opening over Another

The portion of the cooling season amenable to ventilative cooling is limited by the climatic conditions at the site. For example, when exterior dry-bulb temperatures are above interior temperatures or when exterior humidity is above acceptable comfort levels, then admission of outside air is detrimental rather than helpful. However, interior air motion can be used even when outdoor conditions are above the comfort limits. ASHRAE *Standard* 55-1981 places the upper limit of the summer comfort zone at 79°F for air at a velocity less than or equal to 50 fpm, but permits extending the limit to 82°F if the air velocity is 160 fpm. Rohles *et al.* (1983) indicate that the summer comfort zone may be extended to as high as 85°F if the mean air speed is 200 fpm.

All ventilative cooling methods require air movement induced by either (1) wind, (2) thermal differences (stack effect), (3) mechanical devices (fan or blower), or (4) some combination of the three. Therefore, the volumetric airflow through the building space must be estimated before the cooling effect is determined. But equations for estimating airflows are based on crude models and further refinements and extensions are still needed.

The seasonal energy savings resulting from ventilative cooling are obtained from integration of the hourly cooling effect, which is straightforward for physiological cooling methods. However, the calculation of structural cooling is more complicated because dynamic thermal mass effects and the coupling of mass to the ventilation air must be included. Simplified methods are not yet available.

Cooling by Air Exchange

Traditionally known as ventilation, the air exchange method replaces warm air from an interior space by cooler outside air. The amount of cooling is computed by the same equation as that used for calculating infiltration losses. The airflow volume for forced

ventilation systems may be estimated from the fan or blower specifications. The airflow rate for wind-driven ventilation can be estimated by

$$Q = 88\, C_v V A \tag{59}$$

where

Q = airflow, cfm
A = free area of inlet openings, ft^2
V = wind velocity, mph
C_v = effectiveness of opening = 0.5 to 0.6 for wind perpendicular to opening and 0.25 to 0.35 for wind diagonal to opening

Chandra *et al.* (1983) give more precise values for C_v for windows on opposite and adjacent walls and for several configurations of interior partitions. The local wind speed V may be estimated from monthly average (or monthly average hourly) data, which may be modified to account for characteristics of the local terrain as described by Vickery (1981).

Airflow volume can also be expressed in terms of external pressures exerted by airflow around a building. Vickery (1981) presents a method to determine this pressure distribution. For buoyancy-driven flow, the airflow rate is expressed by the stack effect, which is modified by a coefficient that accounts for the outlet-to-inlet size ratio.

If no significant internal building resistance exists, and assuming indoor and outdoor temperatures are close to 80°F, the flow due to stack effect is

$$Q = CA\sqrt{H(T_i - T_o)/T_i} \tag{60}$$

where

Q = airflow, cfm
A = free area of inlets or outlets (assumed equal), ft^2
H = height from inlets to outlets, ft
T_i = average temperature of indoor air in height, °R
T_o = temperature of outdoor air, °R
C = constant of proportionality, including a value of 65% for effectiveness of openings. This should be reduced to 50% if conditions are not favorable (C = 7.2).

Equation (60) applies when $T_i > T_o$.

Greatest flow per unit area of openings is obtained when inlets and outlets are equal; Equations (59) and (60) are based on their equality. Increasing the outlet area over inlet area, or vice versa, will increase airflow but not in proportion to the added area. When openings are unequal, use the smaller area in the equations and add the increase as determined from Figure 19.

Equation (60) requires the height from the inlet to outlet, as well as the average temperature of the interior air at this height. Because the stratification in the space depends on many interrelated factors, it is difficult to predict the temperature at this height. Therefore, this temperature is typically estimated as a constant value obtained from an iterative calculation of the energy balance in the space.

Finally, to calculate the cooling effect of the air exchange method, the estimated hourly cooling rates are integrated over the cooling season by using the bin method with concurrent local wind velocities and/or dry- and wet-bulb temperatures. Temperature bins during occupied hours, unoccupied hours, or both are used, depending on the ventilation strategy. Fan power requirements, if any, are deducted to obtain a net cooling effect or to determine a COP for cooling.

Cooling by Air Motion

In this strategy, the amount of cooling depends directly on the air speed achieved in the space. Acceptable comfort can be maintained above the customary comfort zone for air speeds exceeding 50 fpm. Generally, for speeds above 30 fpm, most people will perceive a 15 fpm increase in air speed to be equal to a 1°F decrease in temperature. The permissible upper limits for dry-bulb temperatures should be determined by using the Fanger comfort charts in Chapter 8 that allow for varying conditions of activity, clothing, relative humidity, and air speed.

Cooling airflows can be induced by natural or forced convection. Outside air can be introduced into a space through openings, or fans or blowers can move the air when the exterior air cannot enter because it is too warm or humid. The average air velocity in the space is approximated by the total flow rate divided by the cross-sectional area.

The interior air motion caused by ceiling fans varies as a function of fan position, power, speed, blade size, and the number of fans within the space. Moreover, air speeds within a space can vary drastically at different distances from the fan. Rohles (1983) found that at the level of seated occupants, air speeds of 50 to 200 fpm occurred throughout a 144-ft^2 space with a 52-in. diameter fan. Figure 20 shows typical air speed distribution. Thus, air speeds necessary to extend the upper end of the comfort zone are easily attainable by using approximately one ceiling fan in an average size room in a residential structure.

Airflow rate for blower-, wind-, or buoyancy-driven flows can be determined from the section on air exchange. To calculate the cooling effect of the air motion method, the seasonal cooling energy required at standard comfort zone conditions (no air motion) is determined first using the bin method. Then the cooling required at each temperature bin is calculated with the air motion using the concurrent local air speed and wet- and dry-bulb temperature conditions in the space. These bin data are integrated over the cooling season for occupied and unoccupied hours, with a deduction taken for the required fan energy. The difference between the cooling energy requirements with and without air motion is the net cooling accomplished with the air motion method. The fan energy required to create the air motion, if any, can be used to calculate a COP for cooling.

Evaporative Cooling

Evaporative cooling can be accomplished by direct or indirect systems, or a multistage combination of the two. In a direct system, water evaporates directly into the supply air, resulting in cooling, but increasing the moisture content of the supply air. Indirect evaporative cooling evaporates water into a secondary airstream that exchanges heat sensibly through a heat exchanger, with the primary (supply) airstream. In either case or combination of the two approaches, the amount of cooling depends on the psychrometric conditions of the outside air. Typically, only sensible cool-

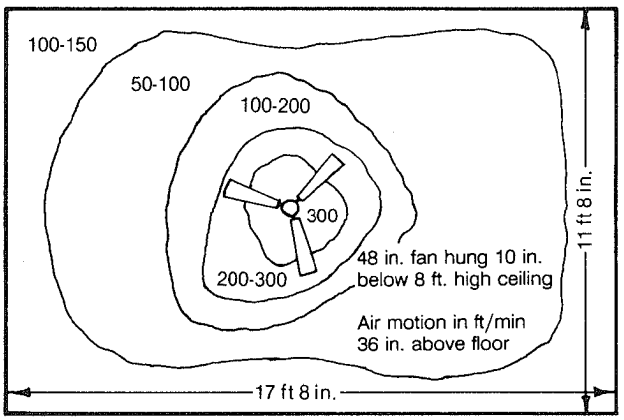

Fig. 20 Approximate Air Speeds from Ceiling Fan

ing is accomplished by these evaporative processes. For a detailed discussion on evaporative cooling, see Chapter 19 of the 1992 ASHRAE *Handbook—Systems and Equipment.*

The performance of evaporative cooling systems is usually determined using a bin method. For each dry-bulb temperature bin, calculate the supply air temperature approach to the mean coincident wet-bulb temperature for the direct evaporative process. For the bin under consideration, the sensible cooling provided by the evaporative system, for sea level air, is given by

$$q_c = 1.10\, Q\, (t_{space} - t_{sa}) \tag{61}$$

where

q_c = cooling rate or space sensible load, Btu/h
Q = airflow rate, cfm
t_{sa} = temperature of air entering space, °F
t_{space} = temperature of space, °F

The system is assumed to be sized so that the cooling capacity meets the design sensible load. If the cooling capacity is insufficient, either auxiliary cooling is required or a higher room air temperature, consistent with the cooling capacity-to-load ratio, should be specified for the bin under consideration.

Next, the fan and pump requirements are determined. Fan power is given by

$$P = 0.12\, Q\Delta p/\eta \tag{62}$$

where

P = fan power, W
Δp = static pressure difference, in. of water
η = combined fan and motor efficiency

Add to this an estimate of the pumping power to obtain the total electrical input to the evaporative cooling unit. The system COP becomes the ratio of the cooling capacity to the electrical input.

Finally, the energy savings rate, compared to a conventional vapor compression refrigeration system, is the difference between the electrical input to the conventional system (cooling capacity/COP for conventional system) and the electrical input to the evaporative system. The energy savings for the bin being considered is the difference in electrical input power multiplied by the number of operating hours for this bin. This calculation is repeated for each bin, and the energy savings, generally expressed in kWh, is summed for the cooling season.

Direct Evaporative Cooling

Residential cooling loads in arid or semiarid regions usually use direct evaporative coolers rather than indirect systems. These direct, open systems are usually sized to meet the full sensible load using once-through airflow (no recirculation of return air). In such cases, the monthly or seasonal energy savings compared to conventional vapor compression cooling can be estimated using the bin method.

Example 6. Calculate the cooling energy savings of a direct evaporative system in a residence in Salt Lake City, UT, for which the bin and load data shown in Table 8 are specified. Assume a 3-ton design sensible cooling load, and that for outside air temperatures < 70°F, ventilation is sufficient to meet this load. The space temperature is to be maintained at 78°F.

Solution: For an assumed evaporative heat exchange effectiveness of 0.85, the supply air temperature for the first bin is

$$t_{sa} = 95 - 0.85\,(95 - 62) = 67°F$$

Thus, the design airflow rate is

$$Q = \frac{(3\text{ tons})\,(12{,}000\text{ Btu/h}\cdot\text{ton})}{(78 - 67°F)\,(1.10\text{ Btu/h}\cdot\text{cfm}\cdot°F)} = 2975\text{ cfm}$$

Table 8 Direct Evaporative Cooling of Residence in Salt Lake City, Utah

Temperature Bin	1	2	3
Dry-bulb temperature range, °F	91 to 100	81 to 90	71 to 80
Average db temperature/Mean coincident wb temperature, °F/°F	95/62	85/57	75/54
Hours of operation at this bin	121	428	471
Sensible cooling load, kW	10.57	7.05	3.52
Sensible cooling provided by evaporative unit, kW	10.57	7.05	3.52
Fan power[a], kW	0.17	0.11	0.06
Pumping power, kW	0	0	0
Total electrical power input, kW	0.17	0.11	0.06
Evaporative system COP	62.2	62.2	62.2
Conventional system power input, kW	4.23	2.82	1.41
Energy savings, kWh	491	1160	635

[a]Equivalent fan power consistent with a constant evaporative unit COP.

at standard summer conditions. Therefore, the evaporative cooling provided for the first bin is by Equation (61)

$$q_c = (1.10)\,(2975)(78 - 67) = 36{,}000\text{ Btu/ or } 10.57\text{ kW}$$

The fan power from Equation (62) is

$$P = 0.12 \times 2975 \times 0.17/0.35 = 173\text{ W}$$

where a pressure drop of 0.17 in. of water is assumed for the evaporative unit. A combined fan and motor efficiency of 0.35, typical for small units, is assumed. If the water to the wetted pad is supplied by line pressure, the pumping power is zero. For the other bins, the evaporative cooling capacity increases while the load decreases. Thus, the unit will cycle to meet the load. The fan power for Bins 2 and 3 has been reduced, consistent with the assumption of a constant COP for the evaporative unit.

For a conventional vapor compression system with an EER = 8.5 Btu/Wh (COP = 2.5) for sensible cooling, assumed to include all appropriate parasitic power, the total electrical input for the cooling load is

$$P = \frac{10.57}{2.5} = 4.23\text{ kW}$$

Thus, the energy savings for this bin are

$$\text{ES} = (4.23 - 0.17\text{ kW})\,(121\text{h}) = 491\text{ kWh}$$

The calculation is repeated (see Table 8) for Bins 2 and 3, resulting in a seasonal energy savings of 2286 kWh.

Indirect Evaporative Cooling

Indirect cooling, or a combination of both, is customarily used with the central fan system because of humidity control requirements in commercial buildings. With indirect evaporative cooling, the wet-side (secondary) air can consist of full outside air or full return air, or any proportion of the two. The bin method illustrated next is applicable to these configurations; however, the details must be modified as appropriate.

If a precise hourly analysis is required, or unusual control strategies or system configurations are used, a system simulation should be applied. The bin method approach requires the calculation of the space load, the return and outside air loads, and the performance and operating power of the indirect evaporative system at each of several dry-bulb temperature bins at the above supply air temperature.

For each dry-bulb temperature bin, first determine the space sensible load using the bin or other suitable method. Next, determine the HVAC system sensible load (cooling coil sensible load) by adding the return air, outside air, and duct sensible loads to the space sensible load. To do this, the supply airflow rate at design

conditions (Bin No. 1) is needed. This is calculated from Equation (61) as

$$Q = \frac{q_c}{1.10\,(t_{space} - t_{sa})} \tag{63}$$

at sea level for fixed space conditions. If the space temperature floats appreciably, the space load and supply airflow rate calculation must take this into account. For a VAV system, this quantity is reduced at the other bins in proportion to the reduced space sensible load.

The return air load (temperature rise) from lighting is calculated from an energy balance on the airflow through the light fixtures as

$$\Delta t = \frac{q_{lighting}}{1.10\,Q_{return\ air}} \tag{64}$$

Similarly, the return air duct gain is estimated. Then the temperature rise of the return air resulting from the introduction of minimum outdoor air (at the outdoor air conditions of the bin under consideration) is determined. The sum of these return air temperature rises, when added to the space air temperature, gives the mixed air temperature. Finally, an energy balance on the mixed air will give the mixed air load. When added to the space sensible load, this gives

$$\text{Mixed air sensible load (Btu/h)} = 1.10\,Q_{sa}\,(t_{mixed\ air} - t_{space}) \tag{65}$$

However, when the outdoor air temperature is lower than the return air temperature and the economizer is in operation, the system sensible load can be calculated as

$$\text{System sensible load (Btu/h)} = 1.10\,Q_{sa}\,(t_{oa} - t_{sa}) \tag{66}$$

plus any fan and/or duct heat gain.

Next, determine the cooling capacity of the evaporative unit. Based on the supply airflow rate through each dry-side core of the evaporative unit, the indirect evaporative heat exchanger effectiveness is assumed to represent the combined wet- and dry-side heat exchange processes. If dictated by the equipment configuration, a two-step heat exchange process can be represented. The temperature drop of the supply air across the dry side of the heat exchanger is then calculated from

$$\Delta t_{sa} = \epsilon\,(t_{dry\text{-}side\ inlet} - t_{wet\text{-}side\ wb}) \tag{67}$$

where ϵ is the effectiveness, $T_{dry\text{-}side\ inlet}$ is the mixed air dry-bulb temperature (when the evaporative unit is located downstream of the economizer mixing box), and $t_{wet\text{-}side\ wb}$ is the wet-bulb temperature of the outside air at mean coincident wet-bulb conditions for the bin (when the wet-side is provided with all outside air). The evaporative cooling capacity is then

$$Q_c = 1.10\,Q_{sa}\,\Delta t_{sa} \tag{68}$$

To determine the operating power, the fan and pump power must be combined. The fan power for each side of the heat exchanger may be calculated by Equation (62). The pressure drop is obtained from the manufacturer's specifications. The pump power is then estimated and added to the fan power to obtain the total electrical input to the system. The system COP is the ratio of cooling capacity to electrical input.

Finally, the energy savings rate, compared to a conventional vapor compression refrigeration system, is the difference between the electrical input of the conventional system and the electrical input of the evaporative system. When these rates are multiplied by the number of hours of operation for each bin and summed for all bins, the seasonal energy savings are obtained.

Example 7. Calculate the cooling energy savings of an indirect evaporative VAV system for a 100-ton design cooling load in a 26,700 ft^2 commercial building in Sacramento, CA, for which the bin data in Table 9 are specified. A two-stage process, indirect evaporative precooling followed by a conventional cooling coil, will be used (see Figure 21). The space air temperature will be maintained at 78°F and the supply air at 60°F.

Solution: For the first bin, the space sensible load is assumed specified as 65 tons. Therefore, the supply airflow rate to meet this load is

$$Q_{sa} = \frac{65 \times 12{,}000}{1.10\,(78 - 60)} = 39{,}4000 \text{ cfm}$$

Table 9 Indirect Evaporative Cooling of Commercial Building in Sacramento, California

[a]Full economizer operation
[b]System outside air (OA) load plus fan and/or duct heat gain

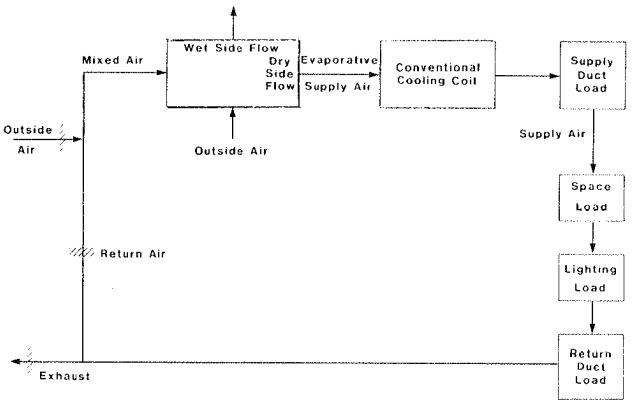

Fig. 21 Indirect Evaporative Cooling System Schematic

The temperature rise resulting from lighting (assume 1.8 W/ft^2) is calculated as

$$\Delta t = \frac{1.8 \times 26{,}700 \times 3.412}{1.10 \times 39{,}400} = 3.8\,°F$$

A temperature rise of 2 °F from duct heat gain is assumed. At an assumed minimum outside air volume of 15% at this bin, energy and mass balances on the mixing of outside and return air result in a mixed air-to-outside air temperature rise of 2.7 °F. Therefore, the mixed air temperature is 78 + 3.8 + 2.0 + 2.7 = 86.5 °F. Thus, the mixed sensible air load is

$$Q_{ma} = 39{,}400 \times 1.10\,(86.5 - 78.0) = 368{,}400\ \text{Btu/h} = 30.7\ \text{tons}$$

and the system sensible load is 65.0 + 30.7 = 95.7 tons.

If the manufacturer of the evaporative cooling unit has specified a heat exchange effectiveness of 52% at this airflow through each core, then the supply air temperature drop through the unit is

$$\Delta t_{sa} = 0.52\,(86.5 - 71.0) = 8.1\,°F$$

The evaporative cooling capacity is then

$$Q_c = 1.10 \times 39{,}400 \times 8.1 = 351{,}100\ \text{Btu/h or } 102.9\ \text{kW}$$

Assuming a specification of a 0.38 in. of water pressure drop across the dry side of the heat exchanger for these flow conditions, 2 hp blower for the wet side, and 75% fan efficiency for each side, the fan power for the dry side is

$$P_{dry\ side} = \frac{0.12 \times 39{,}400 \times 0.38}{0.75} = 2396\ \text{W}$$

and for the wet side

$$P_{wet} = \frac{(2\text{hp})\,(746\text{W/hp})}{0.75} = 1989\ \text{W}$$

If the pumping power is 600 W, the total electrical input is then 2396 + 1989 + 600 = 4985 W = 5.0 kW. Therefore, the system COP is

$$\text{COP} = \frac{102.9}{5.0} = 20.6$$

The energy consumed at this bin for a conventional cooling system, assuming the COP = 3.5, is 102.9/3.5 = 29.4 kW. The energy savings for all hours in this bin are

$$\text{ES} = (29.4\ \text{kW} - 5.0\ \text{kW})\,(11) = 268\ \text{kWh}$$

The calculation is repeated for bins 2 through 5 (see Table 8), and assuming the conventional system uses an economizer cycle (100% OA) for bins 4 and 5, the seasonal energy savings are 26,424 kWh.

Radiative Cooling

Radiative cooling is a natural heat loss mechanism responsible for the formation of dew, frost, and ground fog. Because of its commonly observed effectiveness at night, it is sometimes termed *nocturnal radiation*, although the process continues to operate throughout the day. Thermal infrared radiation plays a role in determining the surface temperature of a building wall or roof, and it has been treated in an approximate manner using the sol-air temperature concept. Radiative cooling of window and skylight surfaces can be significant, especially under winter conditions when the dew-point temperature is low.

The most useful parameter for characterizing the radiative heat transfer between horizontal nonspectral emitting surfaces and the sky is the *sky temperature* T_{sky}. If S designates the total downcoming radiant heat flux emitted by the atmosphere, then T_{sky} is defined as:

$$T^4_{sky} = S/\sigma \tag{69}$$

where $\sigma = 0.1713 \times 10^{-8}$ Btu/(h·ft^2·°R^4).

The sky radiance is treated as if it originates from a blackbody emitter of temperature T_{sky}. The *net radiative cooling rate* R_{net} of a horizontal surface with absolute temperature T_{rad} and a nonspectral emittance ϵ is then

$$R_{net} = \epsilon\sigma\,(T^4_{rad} - T^4_{sky}) \tag{70}$$

Values of ϵ for most nonmetallic construction materials are usually about 0.9.

Radiative building cooling has not been fully developed. Design methods and performance data compiled by Hay and Yellott (1969) and Marlatt *et al.* (1984) are available for residential roof pond systems that use a sealed volume of water covered by sliding insulation panels as the combined rooftop radiator and thermal storage element. Other conceptual radiative cooling designs have been proposed, but more developmental work is required (Givoni 1981, Mitchell and Biggs 1979).

The sky temperature is a function of atmospheric water vapor; the amount of cloud cover and air temperature with the lowest sky temperatures occur under an arid, cloudless sky. The monthly average sky temperature depression, which is the average of the difference between the ambient air temperature and the sky temperature, typically lies between 10 and 43 °F throughout the continental United States. Martin and Berdahl (1984) have calculated this quantity using hourly weather data from 193 sites. They suggest that the sky temperature should be less than 61 °F to achieve reasonable cooling in July (Figure 22). In regions where sky temperatures fall below 61 °F for 40% or more of the month, all nighttime hours are effectively available for radiative cooling systems.

Clark (1981) modeled a horizontal radiator at various surface temperatures in convective contact with outdoor air for 77 U.S. locaions. Average monthly cooling rates for a surface temperare of 76 °F are plotted in Figure 23. If effective steps are taken to reduce the surface convection coefficient by modifying the radiator geometry or an infrared-transparent glazing, it may be possible to improve performance beyond these values.

Design Methods for Daylighting Systems

Estimates of the energy conservation effects of automatic lighting control systems that respond to daylight can be made in conjunction with single-measure cooling energy estimates. Light levels at various locations within the room for both uniformly overcast and sunny days in different seasons can be calculated with procedures recommended by the Illumination Engineering Society (IES 1987) or nomographs (IES 1979, Sain *et al.* 1983). For conditions

in which the daylight level within the space is greater than the design illumination level, electric lights are assumed to be off. Based on these calculations and with knowledge of the distribution of cloudy and clear days, the reduction in hours of artificial lighting and the resultant reduction in lighting energy consumption can be estimated. Effects of solar gain in the space can be calculated using conventional methods.

Reduction of annual lighting energy reduces the annual cooling requirement and increases the annual heating requirement of the building. The simplest method for calculating the reduction in cooling energy is to estimate the coefficient of performance of the cooling system and the number of cooling months during the year. The total reduction from daylighting is equal to

$$E_T = (1 + \frac{M_c}{12\ \mathrm{COP}_c})\ Q_L \qquad (71)$$

where

E_T = annual total energy savings from daylighting
M_c = number of cooling months in year
COP_c = cooling system annual coefficient of performance
Q_L = annual lighting energy savings from daylighting

A more sophisticated method by Robbins (1983) estimates the fraction of the year in which a room is daylit, using a set of coefficients for a given city, orientation, and standard work year. Estimates of cooling energy reduction can be made as shown in Equation (71).

Energy savings estimates from daylighting can be made using somewhat more complex models than the ones just described. Most of these start with the daylighting calculation methodology, otherwise known as the lumen method, adopted by IES (1979) for the estimate of illumination within a room from transmitted daylight. Several programs are available to calculate daylight levels for different room geometries under uniformly clear and cloudy skies (Bryan and Clear 1982). The increased complexity of these methods incorporates seasonal effects of daylight availability and heating and cooling requirements and the effect of lighting control schemes. Lighting and resultant electric lighting savings calculations are made for each month and are incorporated into monthly energy calculations.

After the daylighting contribution in the space has been estimated for a particular exterior condition, the response of the automatic lighting control system is calculated. Automatic lighting controls fall into three categories: simple on-off, sequential stepping of lamps, and continuous dimming (Treado and Kusuda 1980, Gillette 1983). For simple on-off control, artificial lighting is considered to be on, unless the daylighting illumination is greater than the design illumination level within the space.

Calculations for the other two-control schemes use the fact that illumination is additive, and therefore, the supplementary lighting required is merely the daylighting illumination subtracted from the design illumination level. The percentage of supplemental lighting is the supplemental illumination divided by the design illumination (IES 1979). Typical relationships for percentage input power to percentage supplemental lighting are shown in Figure 24 for a continuous dimming system and a four-step sequential control (Gillette 1983). The percentage of input power is multiplied by the design uniform lighting power density in the daylit zone to determine the actual power density for a daylit condition.

Calculations should be performed for numerous solar and sky conditions to determine the daylighting potential over the course of the year, typically on a monthly basis for both clear and cloudy days. Daylight levels can be compared to the actual lighting requirement of the space and the lighting control profile to obtain the actual lighting power density. Monthly weather data, such as that in the *Local Climatological Data* series from NOAA, can be used to determine the number of clear and cloudy days. Lighting power density for clear and cloudy days can be prorated according to these weather data.

Calculations can be made each month to determine the cooling energy decrease and heating increase resulting from daylighting. These calculations can be made in conjunction with a monthly bin method calculation into which the effects of cooling and heating system performance factors are incorporated. This method allows calculations for each month to prorate heating and cooling conditions with daylit and nondaylit periods. Robbins (1983) and Rundquist (1982) have developed methods to reduce the calculations required to estimate daylighting savings.

SIMULATION METHODS

A number of computer programs are available for active and passive solar system analysis. These range from full building energy analysis programs with passive solar capabilities to programs for active solar energy systems, but with some passive and/or hybrid capability. For passive and/or hybrid solar applications in which the details of energy transfer between walls and rooms are required, or for multizone applications in which HVAC system simulation is important, building energy analysis programs are more appropriate. For active solar system studies, or for passive applications for which the nonpassive elements are relatively unimportant, solar simulation programs are appropriate.

Detailed simulation methods can be used for design and energy analysis studies, and in some cases, for HVAC system trade-off

analyses. Advantages are the ability to simulate accurately the details of complex systems, the incorporation of a large variety of system types, and flexibility in doing optimization studies. Disadvantages include the complexity of program input, long running times, high costs, accessibility of computing facilities, and requirements for learning how to use a complex program to perform accurate simulations.

Solar heating and/or cooling simulation programs can be purchased, leased, timeshared, or batch processed. Some programs are proprietary, in which case the user has limited access to program documentation and assumptions, and limited opportunity to change the program to suit special needs. A brief description of the major, accepted simulation programs is provided here. Feldman and Merriam (1979) and Kreider and Kreith (1981) provide more detail on program capabilities.

Building Energy Analysis Computer Programs

Detailed building energy analysis programs, such as those described in U.S. Army (1979) and DOE (1981), were intended for simulation of large, multizone buildings and their HVAC systems. However, they may also be used for active and passive hybrid solar energy analysis. Representative of hour-by-hour simulators, both of these contain active solar system simulators for liquid heating and/or cooling systems; the simulator in LBL (1981) also includes air system capabilities and contains many component models (Roschke *et al.* 1978). Using these components, the user can assemble a system to suit special requirements or select a preassembled, standard liquid-to-air system from among several in the program library. To save time, most users use a preassembled system. Both commercial and residential building systems, including space heating and cooling, process hot water, and combined solar heat systems, are modeled.

These detailed building energy analysis programs can also be used for passive-hybrid system analysis. They include detailed evaluations of solar and other thermal energy exchanges inside the structure. Transfer function techniques are used to simulate the dynamics of heat flow through walls, roofs, and other envelope structures. In the program described in U.S. Army (1979), radiation exchange between surfaces and convection between walls and room air are included. An energy balance is used to compute surface and room temperatures. Another approach to calculating loads is used in the program described in LBL (1981). Here the loads are calculated assuming a constant temperature in the conditioned space. The thermal storage effect is simulated by applying weighting factors to internal and solar gains; custom weighting factors may be generated for the building being analyzed. The effect of assuming a constant space temperature is corrected by a perturbation technique in the next stage of the program when the heating and cooling system is simulated, although the load predictions of these two programs agree closely when custom weighting factors are used. The approach that uses an energy balance on each space can simulate temperatures more accurately in spaces where conditions fluctuate widely under the influence of solar gains. While these programs provide a detailed picture of thermal energy flows and the interaction between the heating and cooling load and equipment, they include simplifications that may not fully account for all significant energy terms.

Both programs are flexible and can accommodate passive components such as direct gain and storage walls. External shading devices and the transmittance of the glazing are accurately computed. An accurate simulation of a passive structure can be made. One disadvantage of these programs may be the large amount of input information required to simulate a simple passive structure. Many applications require a significant level of detail and may require an analyst with training or experience in computer simulation.

Solar Heating and Cooling Simulation Methods

The transient solar system simulation program described by Klein *et al.* (1976) has been developed for analyzing active solar heating and cooling systems. It is a modular program, with each module representing a specific physical component. The standard library contains component models for collectors, storage devices, heat exchangers, heat pumps, controllers, and so forth. The building load components include walls, roofs, and windows that can be used to build up to a complete structure and can also be a component for modeling internal rooms. Passive elements, such as direct gain and storage walls, are also part of the library. The components needed for simulating active and passive systems are provided.

The components are connected in a manner analogous to the actual system, which allows any solar system configuration to be specified and modeled. Passive elements can be connected into the system in the same way as active elements. The building loads calculations are less sophisticated than those of comprehensive building energy analysis programs.

Another active solar system program described by Arumi-Noe and Northrop (1979) simulates system performance for a representative day each month. It is not as flexible as full building energy analysis computer programs. Nor is it modular, and the user lacks the freedom to build simulation models of nonstandard solar systems. It is more flexible than the *f*-Chart method, since it includes several types of solar systems that are not included in the *f*-Chart. This program includes tracking and concentrating collector solar cooling systems, in addition to conventional heating systems on which the *f*-Chart is based.

Other special-purpose computer programs, both proprietary and public domain, are available for active solar system simulation. For descriptions of these and other programs, as well as accessibility, see Feldman and Merriam (1979) and Kreider and Kreith (1981).

Thermal network programs, which are less sophisticated and comprehensive than building energy analysis programs, may be more suitable for simulating passive-hybrid solar buildings. Representative programs are presented in McFarland (1978) and Berkeley Solar Group (1982). These programs were intended for residential and light commercial HVAC systems limited to a furnace or central air conditioner. They treat the building as having one or two thermal zones. The basis of the calculation procedure is a thermal network that connects all elements with thermal resistances. Energy balances are performed on each mass element, and the resulting equations are integrated over time. The programs readily accommodate common passive components such as direct gain and storage walls, sunspaces, underfloor rock beds, and natural ventilation. A minimum of input data is required.

Another hour-by-hour analysis tool for passive systems is a modular program that uses a thermal network, finite-difference solution procedure (Arumi-Noe and Northrup 1979). Graphical output routines are included in the program. Although developed primarily for residential passive heating applications, this program can treat multizone buildings and has limited passive cooling and daylighting capabilities. However, HVAC system simulation capabilities are limited.

Simplified passive solar analysis programs, based on fixed and limited system configurations and a small number of thermal nodes, have been developed. Examples are described in Nordham (1981), Milne and Yoshikawa (1979), and Kohler and Sullivan (1980). Because of the simplified algorithms employed, the results of these programs are not likely to be as accurate as detailed simulations are. However, they require fewer inputs and computer resources.

Because of their modularity, building energy analysis computer programs and thermal network programs can, in principle, simu-

late passive-hybrid cooling options based on ventilation, evaporation, and radiation. Most of the algorithms in the available programs that represent passive cooling processes are fairly crude. For example, a number of the widely used programs include first-order air-exchange natural ventilation models; others include evaporative cooler models as well (Berkeley Solar Group 1982). None of these as yet includes roof pond, central system evaporative, or radiative cooling models that are coupled to the space air temperatures and/or include thermal cool storage effects. Several detailed models of wet and dry roof ponds, which include coupling and storage effects, have been developed (Loxsom *et al.* 1983); however, none is well documented or in widespread use.

Daylighting Simulation Methods

Simulation of daylighting is important to evaluate (1) the reduction of electricity used for lighting, and (2) associated thermal effects, which can impact the heating and cooling loads of a building. The thermal impacts of daylighting vary considerably, depending on electric lighting power density and control, window size, transmittance, placement, and climate (Place *et al.* 1987, Johnson *et al.* 1984, Arasteh *et al.* 1985). Adverse cooling impacts due to excessive solar gain can be limited by a daylighting system that prevents acceptance of more daylight than is useful for offsetting electric lighting. Careful design can reduce both cooling energy consumption and peak cooling demand. Adverse heating impacts can be minimized by using insulating windows and avoiding glazing areas that are larger than necessary.

Availability of daylight has not been measured in enough locations over sufficient time to be directly applied in most simulations. Because of the different proportions of solar heat and light with variations in sun altitude and atmospheric conditions, undifferentiated solar radiation data cannot be used directly in daylighting simulations either. Nevertheless, Littlefair (1985) found that this proportion, the luminous efficacy, which usually varies from about 70 to 130 lm/W, can be applied to the direct and diffuse components of solar radiation to estimate the light available under given conditions. For tables of available daylight, refer to Robbins (1986).

Controls affect the efficiency of the daylighting system, especially its impact on heating and cooling in a building. Aperture controls, such as drapes, blinds, insulating shutters, etc., moderate the amount of light entering an aperture and/or contribute to the insulating value of the glazing. They maximize useful solar heat gains and reduce thermal losses through the glazing. In cooling situations, they can permit just enough light to assure proper visibility in the space. This technique can assure lower cooling loads and limit peak demand. Aperture controls can also ameliorate daylight discomfort glare and prevent penetration of beam radiation onto the workplane.

Electric lighting controls adjust electric light levels based on the quantity of daylight available. Lighting controls can be of either the dimming or switching type. With a switching system, lights near windows or skylights are switched off when daylight in these areas exceeds some threshold value. With dimming systems, the light levels are sensed by a photoelectric cell that dims the electric light in proportion to the amount of available daylight. The mechanism that controls the electric lights can be either automatic or manually operated or a combination of the two. Crisp (1981) found that while occupants may switch on lights when daylight is insufficient, they do not ordinarily switch them off when daylight is adequate.

In simulating daylighting, a comprehensive daylighting system should be integrated with other elements of the building design, especially HVAC systems, the building structure, roof and wall sections, and interior design. A variety of daylighting simulation techniques and products are available, ranging from tables and nomographs to computerized methods (Wilde 1985). Many techniques develop information on illumination and/or electric lighting response to be passed on to a more general building energy analysis procedure.

Cole *et al.* (1983) describe the Illuminating Engineering Society's (IES) daylighting calculation procedure (the lumen method), which may be used in an hour-by-hour program to estimate daylighting levels in a room. The electric lighting power density is then calculated each hour as a function of the supplementary illumination required. This function can be modified to reflect various lighting control techniques described earlier. Although the IES procedures have very specific limitations on the configuration of a room and its fenestration in the calculation assumptions, the calculation is simple and can be repeated without significant expense in computer time.

Another approach documented by Gillette (1983) and Jurovics (1979) uses explicit, but simplified geometric calculations to estimate the hour-by-hour illumination at a specific point in a room. The most advanced method using this approach has achieved good approximations of illumination levels compared with test models (Gillette 1983). Supplemental illumination requirements for each hour are then compared with the lighting control function to determine the lighting power required.

A third approach uses data from a separate illumination calculation computer model (Dilaura and Hauser 1979) or instrumented physical models to develop simple linear models of illumination level in a room (Davenport and Nall 1983). Statistical analysis is used on resulting data to develop a regression model of the illumination level in a space as a function of exterior solar conditions. The linear statistical model is then used to estimate daylighting illumination in the space. The control system response can be precalculated to develop a profile of lighting power density against specific levels of daylight illumination in the space. Switching schemes can be input as a step function with the discontinuities at the illumination levels that initiate switching.

Daylighting simulation methods have been combined in various ways with hourly building energy analysis programs. One approach described by Winkelmann and Selkowitz (1986) and Herron *et al.* (1981) integrates routines that determine daylight illuminance and simulate lighting and aperture controls directly in the loads calculation. In this approach, the illuminance calculation may be based on a geometric calculation such as that described earlier, or it may be calculated from empirically determined factors that correlate daylight illuminance with transmitted solar gain from room apertures. Another approach is to use an illuminance calculation program as a preprocessor to determine effective electric lighting schedules for use in a separate loads program (Treado *et al.* 1986). With either approach, the hourly reduction in electric lighting power due to daylighting is used in the thermal calculation, so that the impact of daylighting on heating and cooling loads, electricity consumption and demand, and HVAC equipment sizing can be determined.

CHAPTER 29

COOLING AND FREEZING TIMES OF FOODS

Theoretical Methods 29.1
Semitheoretical Methods 29.8
Empirical Formulas for Estimating Cooling Time 29.8
Sample Problems for Estimating Freezing Time 29.12
Symbols 29.14

THIS chapter reviews selected procedures available for estimating heat conduction that occurs during the cooling, freezing, and thawing of foods. These procedures may be classified as *semitheoretical* or *theoretical*. Semitheoretical methods combine experimental data and heat balance equations; theoretical methods rely solely on mathematical solutions. Examples in the chapter use selected procedures to estimate cooling or freezing time.

THEORETICAL METHODS

Most theoretical models use heat conduction equations similar to Fourier's equation. Simple geometrical shapes can be solved analytically, but complex shapes require numerical solutions. This chapter classifies theoretical methods as (1) those assuming that freezing or defrosting completes at a single temperature and (2) those assuming that the phase change completes over a range of temperatures.

Phase Change at Single Temperature

Plank's formula (1941) is widely used because of its mathematical simplicity. It can only be used to estimate freezing or defrosting time, and it gives no information on transient temperature distribution. It was derived analytically by assuming conditions B2, I1, P2, and M1 as defined in Table 1. In addition, the surrounding medium is assumed to be in a steady-state condition. Plank's formula, Equation (1), applies to samples with infinite slab, infinite cylinder, spherical, or rectangular parallelepiped configurations.

$$\theta_f = \frac{L\rho}{|t_f - t_a|}\left(Pd/h + Rd^2/k\right) \qquad (1)$$

To use Plank's equation for freezing, k and ρ should be the values of frozen food, since heat is removed through a frozen layer. In thawing, the property values of unfrozen food should be used. The following table shows values of P and R for the shapes indicated.

Shapes	P	R
Slab	1/2	1/8
Cylinder	1/4	1/16
Sphere	1/6	1/24
Rectangular parallelepiped[a]	See Figure 1	See Figure 1

[a]Figure 1 shows P and R values for food of dimensions d by $\beta_1 d$ by $\beta_2 d$. In this figure, β_1 and β_2 are interchangeable, since P and R curves are symmetric with respect to the 45° diagonal line.

Ede (1949) prepared charts to simplify the estimation of freezing time of food of brick-shape (rectangular parallelepiped).

Even though condition I1 was assumed, the formula is applicable to condition I2, as Plank originally suggested. For this application, latent heat of the phase change in the equation is replaced with total heat required for completing freezing or thawing as used by Earle and Fleming (1967) and Nagaoka *et al.* (1955). Scott and Hayakawa (1977) prepared a set of charts for the determination of phase change time by using Plank's formula.

Table 1 Classification of Restrictive Assumptions Imposed for Deriving Analytical or Numerical Solutions of Heat Balance Equations

Code No.	Condition	Assumption
B1	Boundary conditions	Given surface temperature of sample object or infinitely large Biot number.
B2		Convective heat exchange between surrounding medium and surface of sample or finite Biot number.
B3		Radiative heat exchange between radiative heat source and surface of sample object.
B4		Prescribed heat flux on surface.
B5		Moisture loss or gain on surface.
I1	Initial condition	Constant initial temperature of sample object, identical to a phase change temperature or identical to upper or lower limit of phase change temperatures.
I2		Constant initial temperature of sample object, different from phase change temperatures.
I3		Location variable initial temperatures, different from phase change temperatures.
D1	Density of sample object	No difference in density between frozen and unfrozen samples. Temperature-independent density.
D2		Difference in density between frozen and unfrozen samples. Temperature-independent density.
D3		Similar to D2. Temperature-dependent density.
P1	Other physical properties	Temperature-independent properties. Properties of frozen sample different from those of unfrozen sample.
P2		Temperature-dependent properties.
M1	Movement of unfrozen mass	No convective nor diffusional movement of unfrozen mass of sample.
M2		Convective movement of unfrozen mass or solute owing to volumetric change.
M3		Diffusional movement of unfrozen mass or solute owing to its concentration gradient.
M4		Both of M2 and M3.

The preparation of this chapter was assigned to TC 11.9, which is presently inactive.

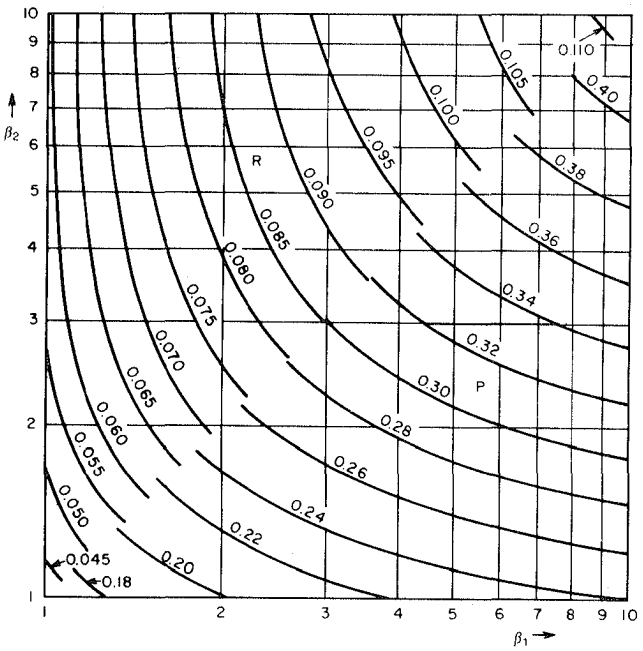

Fig. 1 *P* and *R* Values for Brick Shape
(Ede 1949)

Chung and Yeh (1975) considered heat conduction in a semiinfinite body. They assumed conditions B2, B3 (simultaneous convection and radiation on the surface of the sample), I1, D1, P1, and M1. They reduced Fourier's partial differential equations by applying Biot's variational method or Goodman's integral method. Even though the ordinary differential equations are not suitable for deriving analytical expressions, they may be easily solved by using any proper numerical integration procedure.

Yuen (1980) obtained approximate, analytical solutions for locating a melting front and temperature distribution in a semiinfinite body by assuming B1, B2, or B4, as well as I2, D1, P1, and M1. He also assumed that the product of specific heat and density did not change with the phase conversion. He used Goodman's integral method to obtain these formulas. The formulas obtained by assuming B1 and B4 are closed form are relatively simple and could be used if his assumed conditions are met. The formula for assumption B2 is in the form of a nonlinear ordinary differential equation that should be solved numerically. Lunardini (1983a, 1983b) obtained approximate, analytical solutions in a closed form for freezing or thawing a semiinfinite body. His assumptions are identical to Yuen's, except for a change in the product of specific heat and density with the phase change. Lunardini observed that results obtained from his solutions agreed with available exact or approximate solutions.

The initial temperature distribution in some sample bodies is not uniform. Therefore, Lunardini (1983a) obtained an analytical solution for estimating transient state temperature distribution in a semiinfinite body. The solution represented the initial temperature distribution as the linear function of the location variable (assumed as an I3 condition). The other conditions assumed were B1, D2, P1, and M1.

Lunardini (1983b) considered the expansion of water when it freezes, to derive an approximate, analytical solution for freezing a semiinfinite body by using assumptions B1, I2, D2, P1, and M1. He used two location variables, x_1 and x_2, to solve the problem. The origin of x_1 is on the current exposed surface, which expands with freezing and shrinks with thawing; x_2 begins on the original surface. The following equations can be used to estimate the temperature distribution in region 1 (the frozen region during freezing and the unfrozen region during thawing) and in region 2 (the unfrozen region during freezing and the frozen region during thawing).

$$t_1 = t_s + (t_{fp} - t_s)\, x_c / X_c \tag{2}$$

$$t_2 = t_{fp} + (t_o - t_{fp}) \left[2\,\frac{x_g - X_g}{\delta - X_g} - \left(\frac{x_g - X_g}{\delta - X_g}\right)^2 \right] \tag{3}$$

where $X_g = 2\,(\rho_1/\rho_2)\,\gamma\,\sqrt{\alpha, \theta}$

$$\delta = bX_g \quad b = \left(\frac{9}{4} + \frac{3\,(\alpha_2/\alpha_1)}{(\rho_1/\rho_2)^2\gamma^2}\right)^{0.5} - 0.5 \tag{4}$$

and where

$$X_c = 2\,\gamma\,\sqrt{\alpha_1\theta} \qquad \gamma^2 = \frac{b_1 - \sqrt{b_1^2 - 4a\,S_T^2}}{2a} \tag{5}$$

$$b_1 = 2S_T[2 + S_T + \phi\,(k_2/k_1)(\rho_1/\rho_2)S_T/(\alpha_2/\alpha_1)] + 4/3\,(\phi k_2 S_T/k_1)^2/(\alpha_2/\alpha_1)$$

$$a = (2 + S_T)[2 + S_T + 2S_T\phi\,k_2\rho_1\alpha_1/(k_1 P_2 \alpha_2)]$$

$$X_c - X_g = 2\,\gamma\,\sqrt{\alpha_1\theta}\;(1 - 2\,\rho_1/\rho_2)$$

In Equation (5), $X_c - X_g$ is either a positive value representing a change in the location of free surface caused by expansion or a negative value caused by shrinkage.

Talmon and Davis (1981) estimated freezing and thawing times of an infinite slab by assuming B2, I2, D2, P1, and M1 and by using a modified isotherm migration method. The estimated freezing or thawing times agreed with published results based on a finite difference procedure.

Charm *et al.* (1972) estimated transient state temperatures of food in an infinite slab or cylindrical shape by numerically solving the heat balance equation that was applicable to each of the imaginarily subdivided layers of the food. The estimation was made by assuming conditions B2, I2, D1, P1, and M1.

Tao (1967, 1968) prepared useful formulas and charts for estimating the phase change time of a body in the shape of an infinite cylinder, infinite slab, or sphere. For this preparation, Fourier's equation for heat conduction was solved numerically by applying a finite difference technique and assuming conditions B2, I1, D1, P1, and M1. The phase change time of a sphere can be computed using Equation (6).

$$\theta_f = 1/6 + f/(3\mathrm{Bi}) + \eta_1 + \eta_2/\mathrm{Bi} - \eta_3 e^{-1/\mathrm{Bi}} \tag{6a}$$

where

$$\eta_1 = 0.096\,[1 - \exp(5.49\,\gamma^3 - 6.62\,\gamma^2 - 4.59\,\gamma)] + 0.176/\mathrm{Bi} \tag{6b}$$

$$\eta_2 = \gamma\,[\,0.024 + 0.179\exp(-2.19\,\gamma)] \tag{6c}$$

$$\eta_3 = 0.051\,[1 - \exp(-2.52\,\gamma)] + 0.104\,\gamma \tag{6d}$$

Kern (1977) examined heat transfer in an infinite slab by assuming conditions B2, I1, D1, P1, and M1. He then derived simple analytical expressions for estimating the upper and lower bounds of true phase change times.

Voller and Cross (1981) examined heat conduction in an infinite cylinder undergoing freezing by assuming B1, I2, D1, P1, and M1. They derived the following simple formula for estimating the freezing time.

$$Fo_f = (0.14 + 0.085\ Y_o) + (0.252 - 0.0025\ Y_o)\ Ld \quad (7)$$

Equation (7) estimated the freezing time with an error of less than 2%, compared to the time estimated by numerical solutions when $0 \leqslant Y_o \leqslant 2$ and $2 \leqslant Ld \leqslant 50$.

Hill and Kucera (1983) obtained an approximate analytical formula for estimating freezing time of a spherical body by assuming B2, I1, D2, P1, and M1.

Rathjen and Jiji (1970) derived approximate analytical formulas to estimate transient state heat transfer and to locate the phase change front in a two-dimensional corner by assuming conditions B1, I1, D1, P1, and M1. They used a superhyperbola to approximate a curve representing the front location. The locations determined by the derived analytical solutions correlated with those determined by solving the original heat conduction equation using a finite difference technique. They also prepared a series of charts for predicting the locations.

Most foods are opaque to thermal radiative heat transfer. However, internal radiative heat transfer contributes significantly to freezing and thawing of some foods such as clear gels or clear solutions, if they are in transparent containers. Chan *et al.* (1986) simulated freezing or thawing of a transparent, semiinfinite body under conditions B1, I1, D2, P1, and M1. They solved the model for several limiting cases, including cases of freezing and thawing by internal radiative transfer with no internal conduction.

A difficulty in solving a heat conduction equation with phase conversion is estimating the location of the freezing or defrosting front as a function of time and temperature distribution. This can be overcome by using enthalpy as a dependent variable, in addition to temperature (enthalpy method). For example, one-dimensional heat conduction with cartesian coordinates becomes:

$$\rho \frac{\delta H}{\delta \theta} = \frac{\delta}{\delta x}\left(k \frac{\delta t}{\delta x}\right) \quad (8)$$

Since enthalpy H depends only on temperature, the above equation can be solved by a proper numerical method. The freezing or thawing front can then be located from estimated enthalpy or temperature distribution.

Shamsunder and Sparrow (1975) used the enthalpy method to examine freezing a square column by assuming B2, I1, D1, P1, and M1. The enthalpy method can be applied to cases of freezing over a range of temperatures.

Several researchers have developed a method for evaluating the flux of unfrozen liquid in a body undergoing freezing or thawing. Although most of these methods are for analyzing the flux in non-foods, they also apply to food freezing.

Shamsunder and Sparrow (1976) modified their previous equation based on the application of the enthalpy method by including an additional term representing changes in enthalpy caused by the movement of unfrozen fluid. This modified equation was used to estimate the formation of cavity in a eutectic fluid undergoing a phase change by assuming conditions B2, I1, D2, P1, and M4.

Tarnawski (1976) investigated heat and moisture transfer in slab-shaped food by assuming conditions B2, I3, D2, P2, and M3. He represented the transfer problems with two simultaneous partial differential equations — Fourier's heat conduction equation and a moisture diffusion equation. He assumed that internal moisture transfer was caused by a gradient in moisture transfer potential, although the volumetric change in the food undergoing freezing or thawing could be one of the major factors responsible for the moisture transfer.

Cho and Sunderland (1974) derived an exact analytical solution for heat conduction in a semiinfinite body by assuming conditions B1, I2, D2, P2, and M2. They assumed that thermal conductivities of frozen and unfrozen material changed linearly with temperature, while condition P1 was applicable to the specific heat.

Grange *et al.* (1976) examined freezing of salt solution in a body whose overall configuration was assumed to be an infinite slab. They also assumed conditions B1, I2, D2, P1, and M4. Their work is unique in that they considered the convective movement of unfrozen water as well as the diffusional movement of the solute. Wollhoever *et al.* (1985) examined theoretically the diffusional transfer of NaCl (condition M3) in an aqueous solution occupied in a semiinfinite space. Assumed conditions for this examination are B1, D2, and P1.

Phase Change over Range of Temperatures

Because most foods do not complete freezing or thawing at one fixed temperature but gradually complete the phase change over a range of temperatures, the mathematical procedures in this section represent heat transfer in food.

Keller and Ballard (1956) estimated transient state temperature distributions in concentrated orange juice by assuming conditions B2, I2, D1, P1, and M1. Schmidt's graphical method was used for this estimation. Using effective thermal conductivity and effective specific heat, which included latent heat of phase change, simplified the computations required.

Tien and Geiger (1967) examined heat conduction in a semiinfinite body by assuming conditions B1, I1, D1, P1, and M1. Because they assumed a phase change over a range of temperatures, a freezing front was replaced with a phase change zone in which there was a mixture of frozen and unfrozen materials. Goodman's integral method was applied to obtain an approximate analytical solution. Tien and Geiger (1968) obtained another set of solutions by assuming time-variable surface temperatures and conditions similar to those in their previous paper. Tien and Koump (1968) reported similar analysis of heat transfer in an infinite slab.

Hayakawa and Bakal (1973) examined heat conduction in an infinite slab and found it necessary to consider the several different combinations of frozen, phase changing and/or unfrozen zones in the slab for the complete evaluation of heat conduction. For each combination of these zones, they derived a set of approximate analytical formulas by applying Goodman's integral technique and assuming conditions B2, I2, D1, P1, and M1. There was agreement between temperatures predicted by most of the analytical formulas and those determined experimentally.

The results of similar analyses were presented by Muehlbauer *et al.* (1973). They simplified the analyses by using apparent specific heat values in which latent heat was included. With this inclusion, the numerical analysis of the heat conduction equation was simplified because there was no need to determine a freezing front.

Tien and Koump (1969) evaluated heat transfer in a semiinfinite body when density changes during freezing or thawing. For this evaluation, they derived approximate analytical formulas by assuming conditions B1, I1, D2, P1, and M2; these are the only available formulas for predicting the influence of the density change on heat conduction, although several researchers have examined this influence by numerically solving the heat and mass balance equations. The application of these formulas for food freezing has been discussed by Hayakawa and Bakal (1973).

Joshi and Tao (1974), as well as Katayama and Hattori (1975), used procedures similar to the enthalpy model technique described by Shamsunder and Sparrow (1975). They obtained solutions by using finite difference techniques. Joshi and Tao (1974) studied heat conduction in lean meat, the overall configuration of which was approximated with an infinite cylinder, by assuming conditions B1, I2, D1, P2, and M1. Shamsunder and Sparrow (1975) presented brief discussions on a mathematical model and then examined heat conduction in sands saturated with water by assuming conditions B1, I2, D1, P1, and M1. The sands were assumed

to be filled either in a semiinfinite space or in an infinite space around a circular pipe. For the former configuration, they also examined the mass flux of unfrozen water by assuming condition D2. This procedure can be applied for freezing porous food.

Mascheroni and Calvelo (1982) developed a method for predicting the freezing time of an infinite plate by assuming B2, I2, D3, P2, and M1. They computed a freezing time by adding precooling, phase conversion, and tempering times. The first and third times were estimated by using analytical solutions of a simple heat conduction equation without phase conversion, the second by numerically solving a nonlinear heat conduction equation. They assumed (1) that precooling terminated when temperature on the midplane between the geometrical center and surface of the plate reached the initial freezing point, (2) that the phase conversion ended when the temperature at the geometrical center reached the initial freezing point, and (3) that the tempering completed when the thermal center reached 14 or 0 °F. They estimated the phase change time by using the following equation:

$$\theta_f = \frac{\rho_w f_{rw} L_w f_{ri} a^2}{(t_{sh} - t_a)k} (k/ha + 1/2) \tag{9}$$

where thermal conductivity of food k is evaluated at the mid-temperature between the initial freezing point and cooling medium temperature.

De Michelis and Calvelo (1982) developed a method for predicting freezing time of an infinite plate where two surfaces were subjected to two different surface heat conductances and/or medium temperatures. Their assumptions were identical to those of Mascheroni and Calvelo (1982).

Cleland and Earle (1979) analyzed heat conduction in food approximated by an infinite cylinder, sphere, or rectangular parallelepiped by assuming B2, I2, D3, P2, and M1 and by using thermophysical property values of the Karlsruhe test substance that has properties similar to lean beef. From this analysis, they obtained the following Plank's-type formula.

$$\theta_f = \frac{\Delta H_v}{t_{sh} - t_a} (P_2 d/h + R_2 d^2/k_s) \tag{10}$$

The values of modified Plank's constants P_2 and R_2 can be estimated by following the two-step calculation below:

Step 1. Calculate P_1 and R_1 from the original Plank's constants, P and R.

$$P_1 = P\,[1.026 + 0.5808\,\mathrm{Pk} + \mathrm{Ste}\,(0.2296\,\mathrm{Pk} + 0.0182/Bl + 0.1050)] \tag{11}$$

$$R_1 = R\,[1.202 + \mathrm{Ste}\,(0.410\,\mathrm{Pk} + 0.7336)] \tag{12}$$

Step 2. Calculate P_2 and R_2 for a respective configuration. For infinite plate:

$$P_2 = P_1 \text{ and } R_2 = R_1 \tag{13}$$

For infinite cylinder and sphere:

$$P_2 = P_1 + 0.1278P \tag{14}$$

$$R_2 = R_1 - 0.1888R \tag{15}$$

For rectangular brick:

$$P_2 = P_1 + P\,[0.1136 + \mathrm{Ste}\,(5.766P - 1.242)] \tag{16}$$

$$R_2 = R_1 + R\,[0.7344 + \mathrm{Ste}\,(49.89R - 2.900)] \tag{17}$$

The above equations are applicable within the following ranges of parametric values:

$0.155 \leqslant \mathrm{Ste} \leqslant 0.34 \qquad 0 \leqslant \mathrm{Pk} \leqslant 0.55$

$0.2 \leqslant \mathrm{Bi} \leqslant 20$ for plate

$0.5 \leqslant \mathrm{Bi} \leqslant 4.5$ for cylinder and sphere

$0.5 \leqslant \mathrm{Bi} \leqslant 22$ for brick

$1 \leqslant \beta_1 \leqslant 4$ for brick

$1 \leqslant \beta_2 \leqslant 4$ for brick

According to Cleland and Earle (1979), differences between freezing time estimated by their formula and determined experimentally were less than 10%. Equation (10) should be limited to substances with properties similar to lean beef.

Hayakawa *et al.* (1983) developed a computer program to simulate two-dimensional heat conduction in anisotropic food of an arbitrary shape by modifying a program developed by Comini and Del Giudice (1976). They assumed conditions B2, B3, B4, B5, I2, D3, P2, and M1. For this development, the following formulas were used to estimate temperature-dependent thermophysical property values, because it was more convenient to use the formulas than tabulated data, and the influence of empirical constants included in the formulas on freezing or thawing rate could be examined.

Density:

$$\rho = f_l \text{ for } t \geqslant t_{sh} \tag{18}$$

$$\rho = \rho_\rho + S_{ds}(t_{sh} - t) + (\rho_l - \rho_r)(t_{sw} - t_{sh})/(t_{sw} - t) \text{ for } t < t_{sh} \tag{19}$$

Apparent specific heat:

$$C = C_l \text{ for } t \geqslant t_{sh} \tag{20}$$

$$C = C_r + E/(t_{sw} - t)^{n_c} \text{ for } t < t_{sh} \tag{21}$$

Anisotropic thermal conductivity:

$$k_x = k_{lx} + S_{klx}(t - t_{sh}) \text{ for } t \geqslant t_{sh} \tag{22}$$

$$k_y = k_{ly} + S_{kly}(t - t_{sh}) \text{ for } t \geqslant t_{sh} \tag{23}$$

$$k_x = k_{rx} + S_{ksx}(t_{sh} - t) + (k_{lx} - k_{rx})(t_{sw} - t_{sh})/(t_{sw} - t) \text{ for } t < t_{sh} \tag{24}$$

$$k_y = \gamma k_x \text{ for } t < t_{sh} \tag{25}$$

where

$$k_{ly} = \gamma k_{lx} \tag{26}$$

Note that Equation (24) can be used to estimate y-directional or isotropic thermal conductivity if the empirical parameters included in this equation are replaced with theoretical parameters. For example, to estimate y-directional conductivity, replace k_{rx}, S_{ksx}, and k_{lx} with k_{ry}, S_{ksy}, and k_{ly}, respectively. Because of Equation (26), $k_{ry} = \gamma k_{rx}$, $S_{ksy} = \gamma S_{ksx}$, and $k_{ly} = \gamma k_{lx}$.

The latent heat of the phase conversion is included in Equation (21), which was obtained by slightly modifying Schwartzberg's formula (Schwartzberg 1977). Equation (24) is based on the direct application of Schwartzberg's formula for estimating thermal conductivity at temperatures below the highest freezing point t_{sh}. According to available data, the ratio of thermal conductivities

parallel and perpendicular to muscle fibers is almost constant when $t \leqslant t_{sh}$; therefore, Equation (25) is used.

Hayakawa *et al.* (1983) examined the influence of all independent parameters on freezing food thermophysically approximated with an infinite rectangular column or finite cylinder. For this examination, they used the maximum range of values of empirical constants in Equations (18) through (26) and also of operational parameters for commercial freezing such as freezing medium temperature, initial and final food temperatures, surface heat conductance, rate for moisture loss, and radiative heatsink temperature.

To simplify computations, the following dimensionless expressions were used.

Dimensionless density:

$$Pd = \begin{cases} Rd + 1 \text{ for } U \geqslant U_{sh} & (27) \\ 1 + Md\,(U_{sh} - U) + Rd/(D_a - UD_b) \\ \text{for } U \geqslant U_{sh} & (28) \end{cases}$$

Dimensionless apparent specific heat:

$$Pc = \begin{cases} Rc + 1 \text{ for } U \geqslant U_{sh} & (29) \\ 1 + C_{eh}/(D_a - UD_b)^{n_c} \text{ for } U < U_{sh} & (30) \end{cases}$$

Dimensionless thermal conductivity:

$$P_{kx} = \begin{cases} 1 + R_{kx} + M_{klx}\,(U - U_{sh}) \text{ for } U \geqslant U_{sh} & (31) \\ 1 + L_{kx}\,U - M_{klx} + R_{kx}/(D_a - UD_b) \\ \text{for } U < U_{sh} & (32) \end{cases}$$

$$P_{ky} = \begin{cases} 1 + R_{ky} + M_{kly}\,(U - U_{sh}) \text{ for } U \geqslant U_{sh} & (33) \\ \gamma\, P_{kx} \text{ for } U < U_{sh} & (34) \end{cases}$$

According to statistical analysis of the computed results, the following parameters influenced dimensionless freezing time Fo_f significantly for both configurations: U_o (initial food temperature), U_a (freezing medium temperature), U_f (final food temperature), U_{sh} (initial freezing point of food), C_{eh} [constant in Equation (30)], Bi_u (parameter applicable to the three sides of an infinite rectangular column or applicable to the top and side surfaces of a finite cylinder), Bi_n (parameter applicable to remaining surfaces of both configurations), and Sf (shape factor). For rectangular food, Sf is the ratio of two sides; for cylindrical food, it is height/radius.

The freezing time was not influenced significantly by the radiative source temperature, absorbance of radiative energy, temperature dependence of thermal conductivity, anisotropy in thermal conductivity, temperature dependence of density, or rate of surface moisture loss or gain.

Through further analysis of computational results, Hayakawa *et al.* (1983) obtained the following formulas for estimating freezing time.

Rectangular food:

$$\begin{aligned} \ln (Fo_f) = {} & 2.454463 + 0.032643\,X_o - 0.240336\,X_a \\ & - 0.257882\,X_{sh} + 0.070507\,X_f + 0.292865\,X_{eh} \\ & + 0.830827\,X_{iu} + 0.257515\,X_{in} + 0.070274\,X_{sf} \\ & - 0.012814\,X_o^2 - 0.051904\,X_a^2 - 0.078139\,X_{sh}^2 \\ & - 0.056448\,X_{eh}^2 + 0.067824\,X_{iu}^2 - 0.028723\,X_{in}^2 \\ & - 0.068525\,X_{sf}^2 - 0.030382\,X_aX_f + 0.013005\,X_fX_{eh} \\ & + 0.021406\,X_{in}X_{sf} + 0.096347\,X_{iu}X_{in} - 0.015276\,X_{sh}^3 \\ & - 0.004532\,X_{eh}^3 - 0.010683\,X_{iu}^3 - 0.006472\,X_{in}^3 \\ & + 0.0016285\,X_{sf}^3 \end{aligned} \quad (35)$$

Table 2 Minimum, Frequent, and Maximum Values of Significant Parameters

Parameter	Minimum	Frequent	Maximum	Variables in Eqs. (35) and (36)

[a]Negative U_a is used for transformation to the design variable X_a [b]Rectangle [c]Cylinder

Cylindrical food:

$$\begin{aligned}\ln (Fo_f) &= 2.298986 + 0.035752 X_o - 0.229786 X_a \\ &- 0.258789 X_{sh} + 0.078752 X_f + 0.291006 X_{eh} \\ &+ 0.777841 X_{iu} + 0.070700 X_{in} + 0.137491 X_{sf} \\ &- 0.035143 X_a^2 - 0.068954 X_{sh}^2 + 0.011703 X_f^2 \\ &- 0.038801 X_{eh}^2 + 0.137763 X_{iu}^2 - 0.129691 X_{sf}^2 \\ &- 0.028044 X_a X_f + 0.010418 X_f X_{eh} - 0.01739 X_f X_{iu} \\ &+ 0.037177 X_{iu} X_{in} + 0.028813 X_{iu} X_{sf} \\ &- 0.036392 X_{in} X_{sf} - 0.016211 X_{sh}^3 - 0.006843 X_{iu}^3 \\ &- 0.004018 X_{in}^3 - 0.037937 X_{sf}^3 \end{aligned} \quad (36)$$

Equations (35) and (36) only apply when the parametric values are within their respective minimum and maximum values shown in Table 2. Since these equations were obtained through the regression analysis of computational results obtained by applying a statistical procedure, they use variables transformed from the significant parameters by using the following equation:

$$X_x = G_1 \ln (\pi_x + G_3) + G_3 \quad (37a)$$

where π_x is any significant parameter, and X_x is a transformed variable.

Constants G_1, G_2, and G_3 in Equation (37) can be estimated from the minimum, frequent, and maximum values shown in Table 2 by using the following equation:

$$\begin{aligned} G_1 &= 5.6568/\ln [(\pi_{x,max} + G_2)/(\pi_{x,min} + G_2)] \\ G_2 &= (\pi_{x,max}\pi_{x,min} - \pi_{x,frq}^2)/(2\pi_{x,frq} - \pi_{x,min} - \pi_{x,max}) \\ G_3 &= -G_f \ln (\pi_{x,frq} + G_2) \end{aligned} \quad (37b)$$

It is useful to know the magnitude of error in estimated freezing time when there are errors in the significant variable values. Table 3 shows the results of error analyses performed by using Equations (35) and (36) at the frequently observed or practiced levels of significant variables. Case 1 is an analysis performed by assuming 1.8°F error in initial and final food temperatures, 3.6°F error in a freezing medium temperature, 5% error in specific heat variables, 10% error in thermal diffusivity, 10% error in Biot numbers, and 0.04-in. error in food dimensions. With these reasonable errors, the maximum errors are less than 60%—one-third of which can be attributed to errors in specific heat parameters. Case 2 results were obtained by reducing the errors of operational temperatures, specific heat parameters, and thermal diffusivity to one-fifth of those for Case 1, which is possible when data on these properties are accurate. Reduction of the other errors is almost impossible. Even with errors of small magnitude, maximum errors are less than 25%. Any error caused by the *method* used to estimate freezing time would be additional to those stated above.

Table 3 Relative Errors of Estimated Freezing Times[a]

	Rectangle		Cylinder	
Source of Errors	Case 1[b]	Case 2[c]	Case 1	Case 2
Operational temperature	10.9 (%)	2.2 (%)	7.7 (%)	1.5 (%)
Food dimension	7.6	7.6	5.1	5.1
Thermophysical property	30.4	6.1	30.4	6.1
Boundary property	8.4	8.4	5.6	5.6
Total	57.3	24.3	48.6	18.3

[a]Relative error = $100 \frac{\text{Error in estimated freezing time caused by source error}}{\text{Estimated freezing time}}$

[b]Error analysis based on large source errors.

Table 4 (Succar and Hayakawa 1983) shows parametric values useful in applying Equations (35) and (36). The freezing times estimated by these equations fluctuate with an increase in Bi for some combinations of parameters instead of monotonic reduction, and care should be exercised in their application.

A computational method for estimating freezing time cannot determine thawing time when physical properties vary with temperature. Therefore, Nonino and Hayakawa (1986) developed formulas for estimating the thawing time of food thermophysically, approximated by an infinitely long rectangular column or a finite cylinder. The conditions assumed for this development are identical to those applicable to Equations (35) and (36). The overall approach to this development is similar to the approach of Hayakawa *et al.* (1983). Dimensionless groups influencing thawing time significantly were identical to those included in Equations (35) and (36).

Succar and Hayakawa (1984) developed a formula for estimating freezing time of an infinite slab whose surfaces were subjected to convective and radiative heat exchange with a surrounding environment (conditions B2 and B3). The convective surface heat conductance and radiative adsorbance of one surface was assumed to be different from respective physical parameters of another side (nonsymmetric freezing). Additional assumed conditions are I2, D3, P2, and M1.

The developed formula is as follows:

$$\begin{aligned}\ln (Fo_1) &= 2.5949 + 0.0222 X_o - 0.2117 X_a - 0.2181 X_{sh} \\ &+ 0.05161 X_f + 0.249 X_{eh} + 0.770 X_{iu} + 0.2411 X_{in} \\ &- 0.3756 X_f^2 + 0.0507 X_{in}^2 + 0.083 X_{in} X_{iu} \\ &- 0.0092 X_{sh}^3 - 0.0107 X_{iu}^3 - 0.0044 X_{sh}^4 + 0.0334 X_f^4 \\ &- 0.0028 X_a^4 - 0.026 X_{eh}^4 - 0.0010 X_{in}^4 \end{aligned} \quad (38)$$

where $Fo_1 = \alpha t/d^2$.

The values of X_o, X_a, X_{sh}, X_f, and X_{eh} may be estimated by using values given in Table 2 and Equation (37a). The values of G_1, G_2, and G_3 in Equation (37a) were estimated by using the set of equations obtained from Equation (37b) by replacing the constant of the first equation, 5.6568, with 3.76374. The values of X_{iu} and X_{in} are estimated by:

$$X_{iu} = 0.72720 \ln (1/Bi_u + 0.005845) - 0.26307 \quad (39)$$

$$X_{in} = 1.54552 \ln \left[\frac{1/Bi_n + 0.05664/Bi_n + 0.0084}{0.96275/Bi_u + 0.14263}\right] \quad \text{for } 0.0082 \leq 1/Bi_u + < 1.43 \quad (40)$$

$$X_{in} = 1.54552 \ln \left[\frac{1/Bi_n + 0.006168/Bi_n + 0.08054}{0.10487/Bi_u + 1.369396}\right] \quad \text{for } 1.43 \leq 1/Bi_n + < 146.4 \quad (41)$$

Equation (38) may be used to estimate nonsymmetric freezing time of an infinite slab. This equation was obtained by assuming a frequently observed level of radiative heat adsorbance (0.8), since the radiative surface heat transfer did not influence the freezing time significantly, according to a parametric analysis. The whole thickness of a slab d was used as the characteristic dimension to calculate Bi_n and Bi_u values included in Equations (39) through (41).

Comini *et al.* (1974) used apparent specific heat, which included the latent heat of phase change, and showed numerical procedures for obtaining finite element solutions by assuming B2, B3, I3, D3, P2, and M1. Specific heat is a strong function of temperature, and its value suddenly increases to a large value at the initial freezing point t_{sh}. Therefore, the error caused by the contribution of latent heat to heat conduction can be overlooked if a functional

Table 4 Selected Empirical Parameters Required to Use Equations (35) and (36)[a]

relationship between apparent specific heat and temperature is used directly. To eliminate this error, Comini *et al.* (1974) estimated apparent specific heat values from enthalpy and temperature distributions around a nodal point.

Although the numerical procedures described are for three-dimensional heat conduction, the sample solutions are for bodies of relatively simple shapes. Comini and Del Giudice (1976) applied similar computerized numerical procedures to estimate temperature distribution in biological tissues during cryosurgery. Rebellato *et al.* (1978) used the same procedures to analyze two-dimensional heat conduction in lamb carcasses and beef sides during airblast freezing.

Fang *et al.* (1984) analyzed transient state heat transfer in an aqueous binary solution, occupying a semiinfinite space and undergoing freezing by assuming conditions B2, I2, D3, D2, and M1. They assumed no mass transfer of solute (M1) because the mass diffusivity was much smaller than the thermal diffusivity.

O'Callaghan *et al.* (1982) and Levin (1980, 1981) estimated solute transport in a solution undergoing freezing by assuming a constant rate of freezing or thermal equilibrium of a sample body with a surrounding medium. Because excessive transport of solute in food results in poor food quality, methods presented in these papers help to evaluate methods for postfreezing handling. However, since most of these researchers assumed a known, con-

stant freezing rate or steady-state temperature distribution in food, these methods cannot be used to predict freezing time.

SEMITHEORETICAL METHODS

Hung and Thompson (1983) obtained Plank-like formulas through the regression analysis of freezing data, which were experimentally collected by using a Karlsruhe test substance (whose thermophysical properties were similar to lean beef). They found that their formulas accurately estimated the freezing times of lean beef, mashed potato, minced carp meat, and ground beef. However, their formulas should be applied carefully to food with properties considerably different from lean beef. Mott (1964) developed a method for predicting freezing times of several different foods. Bailey and James (1974) prepared a chart for estimating the thawing time of frozen pork legs.

Cleland and Earle (1982) modified Equation (10) as follows:

$$\theta_f = \frac{\Delta H_v}{(t_{sh} - t_2)\, W} (P_2 d/h + R_2 d^2/k_s) \qquad (42)$$

where W is an equivalent heat transfer dimension.

The W of a rectangular brick, d by $d\beta_1$ by $d\beta_2$, is estimated by:

$$W = 1 + W_1 + W_2 \qquad (43)$$

where

$$W_i = \left(\frac{Bl}{Bl+2}\right)\left(\frac{5}{8\beta_i^3}\right)\left(\frac{2}{Bl+2}\right)\left(\frac{2}{\beta_i(\beta_i+1)}\right) \qquad (44)$$

where $i = 1$ or 2 and $Bl = hd/k$.

In many situations, freezing medium temperatures t_a and surface heat transfer conductances h change with time during freezing processes. Because most methods readily adoptable for hand-calculations assume constant t_a and h, Loeffen *et al.* (1981) developed two methods applicable to variable medium temperature and conductance; one is based on the numerical integration of Plank's equation for variable t_a and h, and the other is described later.

One freezing process was divided into proper time intervals $\Delta\theta$, during each of which t_a and h were assumed to be constant. By using Equation (10), a freezing time θ_f was estimated for conditions in each time interval. The freezing time for variable environmental conditions was estimated by assuming freezing was completed when the sum of fractions $\Delta\theta/\theta_f$ reached unity. The results obtained by both methods correlated with those predicted by Cleland and Earle's computer program (Cleland and Earle 1979).

EMPIRICAL FORMULAS FOR ESTIMATING COOLING TIME

Although the major emphasis of this chapter is on methods for estimating freezing or thawing time, precooling time is often an important consideration. Therefore, this section covers empirical formulas unique to food processing engineers.

Empirical formulas containing two experimental constants, f and j, are used to predict food temperatures when food is exposed to constant surrounding temperature. These constants were introduced by Ball (1932) to predict temperatures of canned foods during heat processing. Values for f and j represent slope and intercept coefficients, respectively, for a linear portion of a temperature history curve. This curve is obtained by computer analysis or by plotting temperature differences between food and its surrounding medium against a time variable on semilog paper. The f value represents the time required for a linear portion of the history curve to pass one log cycle. The j value is obtained by taking the ratio between the phantom and real temperature differences at zero time. The former temperature difference is obtained by extrapolating the linear portion to a zero time. Formulas containing f and j values can predict a temperature history curve of any food without restriction on shape or heat transfer, if the f and j values are experimentally determined for each food and heating or cooling treatment; the f and j values are independent of an initial temperature difference between food and medium if food is heated by conduction only.

A semilogarithmic temperature history curve always consists of one curvilinear portion and one or more linear portions, except when $j = 1.0$. The following are empirical formulas for estimating food temperatures in both portions (Hayakawa 1982).

Initial curvilinear segment ($0 \leq \theta \leq \theta_v$)

1. $0.001 \leq j \leq 0.4$

$$\Delta t = 10\Delta t - (\theta/B)^{1/u} \qquad (45)$$

$$\theta_v = f(0.3913 - 0.3737 \log j) \qquad (46)$$

$$u = (\theta_v/f - \log j) \,/\, (\theta_v/f) \qquad (47)$$

$$B = \theta_v(\theta_v/f - \log j)^{-u} \qquad (48)$$

2. $0.4 \leq j < 1$

$$\Delta t = \Delta t_o^{\cos(B\theta + \pi/4)} \qquad (49)$$

$$\theta_v = 0.9f(1 - j) \qquad (50)$$

$$B = 1/\theta_v\left[\tan^{-1}\left(\frac{\log \Delta t_o}{\log(j\Delta T_o) - \theta_v/f}\right) - \pi/4\right] \qquad (51)$$

3. $1 < j$

$$\Delta t = \Delta t_o^{\cos(B\theta)} \qquad (52)$$

$$\left.\begin{aligned}\theta_v &= 0.7f(j-1);\ 1 < j \leq 5.8\\ &= 1.54f \log(j/1.8);\ 5.8 < j\end{aligned}\right\} \qquad (53)$$

$$B = \frac{\cos^{-1}}{\theta_v}\left(\frac{\log(j\Delta t_o) - \theta_v/f}{\log \Delta t_o}\right) \qquad (54)$$

Linear portion ($\theta_v \leq \theta$)

$$\Delta t = j\Delta t_o \cdot 10^{-\theta/f} \qquad (55)$$

When a dimensionless temperature ratio is used for the semilogarithmic plot, it is likely that $\Delta t_o \leq 1$ or $\log(j\Delta t_o) \leq \theta_v/f$. In this case, an initial temperature difference Δt_o should be replaced with a hypothetical temperature difference Δt_{oh}, which satisfies:

$$0.2 \leq \log(j\Delta t_{oh}) - \theta_v/f \leq 1 \qquad (56)$$

With this temperature difference, a hypothetical temperature difference Δt_h is estimated by using the appropriate equations among Equations (45) through (54). This hypothetical difference is then converted to an actual temperature difference applicable to Δt_o by:

$$\Delta t = \Delta t_h\, \Delta t_o/\Delta t_{oh} \qquad (57)$$

Half cooling time, value Z, has been used to estimate a cooling time of fresh fruits and vegetables, as described in Chapter 11 of the 1990 ASHRAE *Handbook—Refrigeration*. This Z value is particularly useful when $j = 1$. Otherwise, the temperature response of food cannot be estimated. The following relationship among f, j, and Z values exists if Z is located in the linear portion of a semilogarithmic curve.

$$Z = f \log (zj) \tag{58a}$$

If it is in the curvilinear portion, the proper curvilinear formulas should be used. For example, if $0.001 \leqslant j \leqslant 0.4$:

$$\log Z = \log B - 0.52140\ U \tag{58b}$$

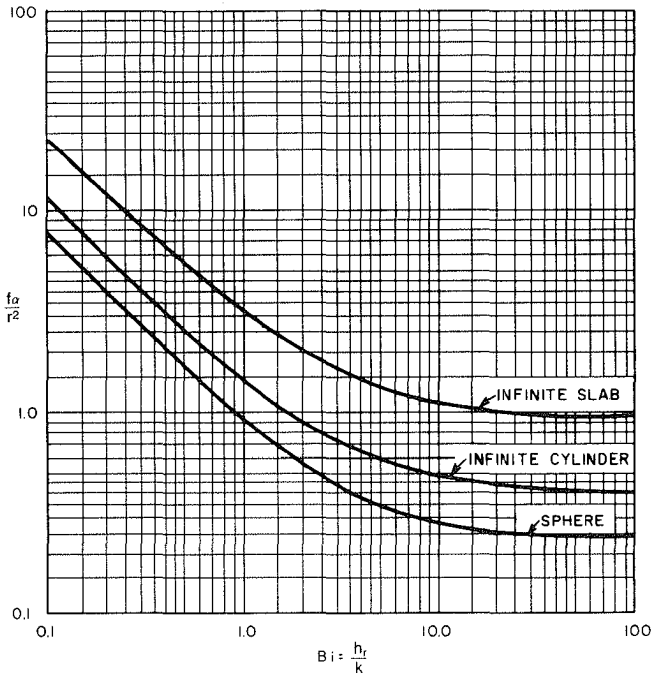

Fig. 2 Relationship between Dimensionless Parameter $f\alpha/r^2$ and Biot Number hr/k for Infinite Slab, Infinite Cylinder, or Sphere
(Pflug *et al.* 1965)

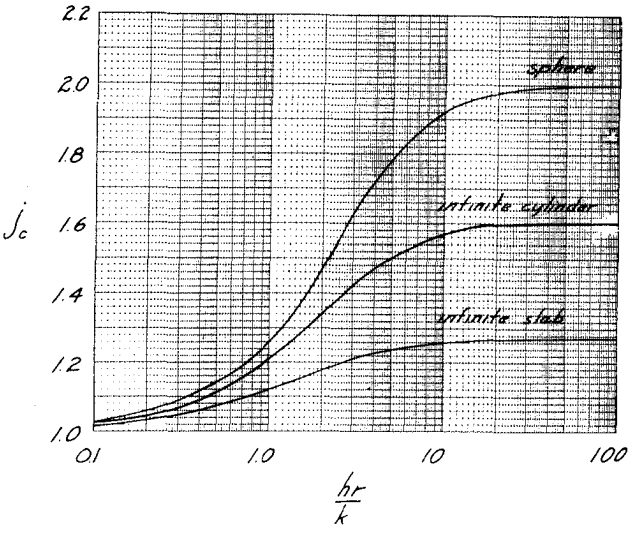

Fig. 3 Relationship between Biot Number hr/k and j Value j_c at Thermal Center of Infinite Slab, Infinite Cylinder, or Sphere
(Pflug *et al.* 1965)

Pflug *et al.* (1965) developed charts for estimating f and j values for conduction heating of food thermophysically approximated with either an infinite slab, infinite cylinder, or sphere. For this development, they used analytical solutions derived by assuming a uniform initial temperature distribution in the body, a constant surrounding medium temperature, convective heat exchange on the surface, constant thermophysical properties, and constant surface heat conductance. Figure 2 is the chart for estimating a dimensionless f value. Figures 3, 4, and 5 are for estimating a j value at the geometrical center of food, a j value for computing volumetric average temperature of food, and a j value on the food surface, respectively. Since f value is location-independent, only one figure estimates this value. In some cases, one side of a slab is insulated, while another side is exposed to a convective medium. In this case, one whole thickness of the slab should be used as the r value for estimating the f and j values using the charts.

The f and j values of the following composite shapes can be estimated using the charts of Pflug *et al.* (1965): (1) infinite rec-

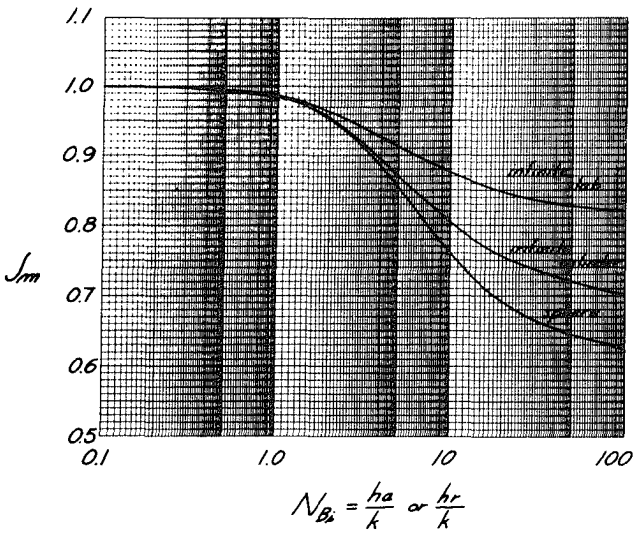

Fig. 4 Relationship between j Value of Mass Average Temperature j_m and Biot Number hr/k for Infinite Slab, Infinite Cylinder, or Sphere
(Pflug *et al.* 1965)

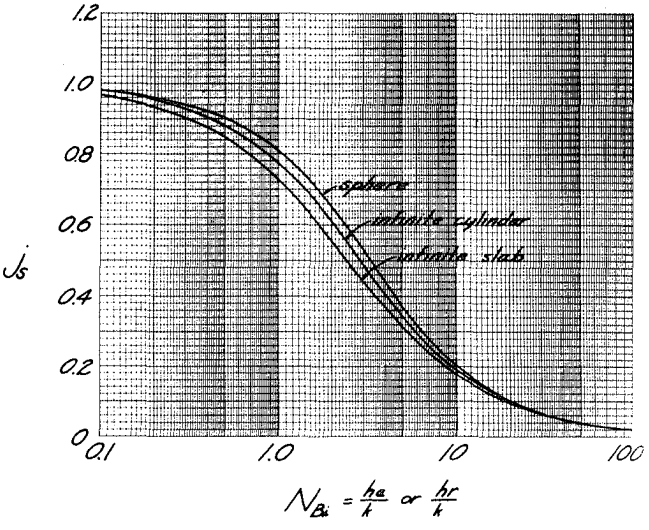

Fig. 5 Relationship between Biot Number hr/k and j Values j_s on Surface of Infinite Slab, Infinite Cylinder, or Sphere
(Pflug *et al.* 1965)

tangular column, (2) finite cylinder, and (3) rectangular parallelepiped (brick).

Each of these shapes can be perceived as volumetric elements produced by intersecting two infinite slabs of proper thicknesses (rectangular column), one infinite slab and one infinite cylinder (finite cylinder), or three infinite slabs of proper thicknesses at right angles to each other (rectangular parallelepiped). The f and j of a composite body are estimated by:

$$1/f_{composite} = \sum_i (1/f_i) \tag{59}$$

$$j_{composite} = \pi_i j_i \tag{60}$$

where subscript i represents f or j values of corresponding infinite slab or infinite cylinder.

The values of the Biot number of corresponding, infinite bodies are all likely to be different, since the characteristic dimensions r of the infinite bodies are different in most cases, although the surface heat conductance h is fixed.

Example 1. Determine the time for the center of a thin slab of meat to reach 40°F, if the slab is thin enough to simulate an infinite slab for which all heat is transferred through the two large parallel faces. The following information is known: t_a = 35°F; t_o = 80°F; t = 40°F; h = 4.0 Btu/(h·ft²·°F); k = 0.35 Btu/(h·ft·°F); r = 0.167 ft; c_p = 0.86 Btu/(lb·°F); and ρ = 64.9 lb/ft³.

Solution:

$$\text{Bi} = 4.0 \times 0.167/0.35 = 1.91$$

$$\alpha = 0.35/(0.86 \times 64.9) = 6.27 \times 10^{-3}\ \text{ft}^2/\text{h}$$

$f\alpha/r^2$ = 2.1 for infinite slab of Figure 2

Therefore:

$$f = 2.1 \times 0.167^2/6.27 \times 10^{-3} \times 9.34\ \text{h}$$

From Figure 3, j_c = 1.17.

By using Equation (55):

$$40 - 35 = 1.17\ (80 - 35)\ 10^{-\theta/9.34}$$

Solve for θ: θ = 9.55 h

Since the equation is used for the linear portion, check that the estimated θ is in this portion. From Equation (53):

$$\theta_v = 0.7 \times 9.34\ (1.17 - 1) = 1.11\ \text{h}$$

Since the solution is greater than θ_v, it is a correct estimation.

Example 2. Consider a package of meat, 0.166 ft by 0.332 ft by 1.0 ft, being cooled under the same conditions as the slab in Example 1. Determine the time at which the center of the package reaches 39°F.

Solution: The package can be considered the intersection of three infinite slabs—0.166 ft, 0.332 ft, and 1.0 ft thick—all mutually perpendicular. Therefore, the value of the Biot number applicable to each slab can be estimated by using 0.083 ft, 0.166 ft, or 0.5 ft as the characteristic dimension. Using these values in Figures 2 and 3, the f and j_c values are obtained for each slab component, as shown below:

Slab	Dimen., ft	Bi	$f\alpha/r^2$	f, h	j_c
1	0.083	0.948	3.4	3.73	1.116
2	0.166	1.90	2.1	9.23	1.17
3	0.5	5.71	1.3	51.8	1.24

By using Equations (59) and (60):

$$1/f = 1/3.73 + 9.23 + 51.8;\ f = 2.53\ \text{h}$$

$$j_c = 1.116 \times 1.17 \times 1.24 = 1.62$$

From Equation (24):

$$39 - 35 = 1.62\ (80 - 35)\ 10^{-\theta/2.53}$$

$$\theta = 3.19\ \text{h}$$

From Equation (52): θ_v = 1.1 h. Since $\theta > \theta_v$, the above estimation is correct.

Smith *et al.* (1968) developed a useful method for estimating the temperature of irregularly shaped food by using a shape factor called the *geometry index G*. This index is defined as:

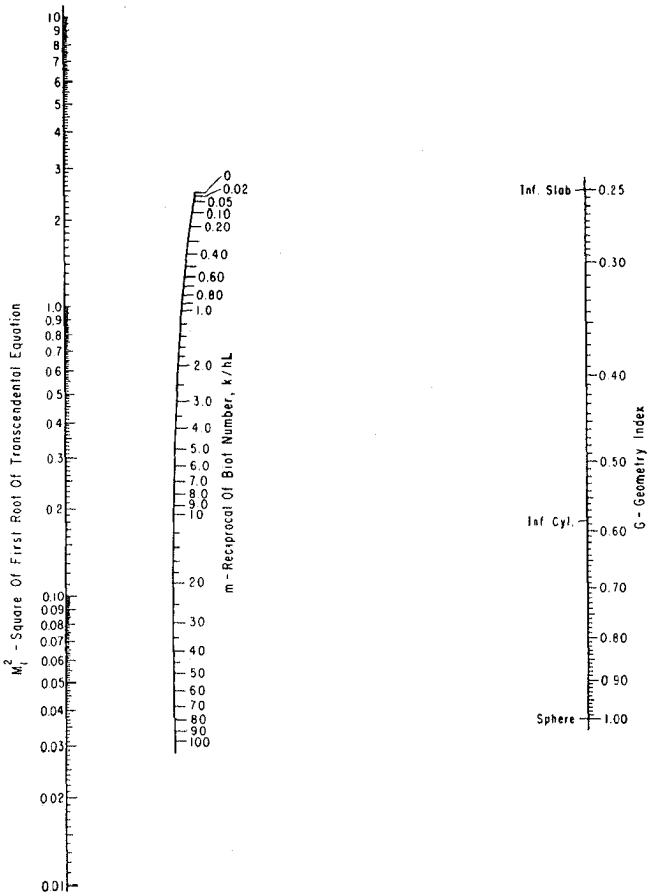
$$G = 1/4 + 3/(8A_1^2) + 3/(8A_2^2) \tag{61}$$

The A_1 and A_2 of Equation (61) are related to the cross-sectional areas of the food, as shown below.

$$A_1 = \text{area } 1/(\pi r^2);\ A_2 = \text{area } 2/(\pi r^2) \tag{62}$$

In the above equation, r is the characteristic dimension of the food, which is the shortest distance between the thermal center of food and its surface exposed to a heat exchange medium. Then, area 1 is the minimum cross-sectional area containing the radial line segment that defines the characteristic dimension. The cross-sectional area orthogonal to area 1 is area 2.

The value of M_1^2, which is related to f, is determined by entering the geometry index and inverse of the Biot number into Smith *et al.* (1968) (Figure 6). Based on the alignment chart of the observed relationship, the following formulas are used to estimate



M₁² - Square Of First Root Of Transcendental Equation
m - Reciprocal Of Biot Number, k/hL
G - Geometry Index
Inf. Slab
Inf Cyl.
Sphere

Fig. 6 Nomograph for Estimating M^2 Value from Reciprocal Biot Number and Smith's Geometry Index
(Smith 1966)

the f and j values estimating the mass average temperature of food.

$$f = 2.303\, r^2/(M_1{}^2\alpha) \tag{63}$$

$$j_{G_m} = 0.892 \exp^{(-0.0388 M_1{}^2)} \tag{64}$$

The use of j_{Gm} produces a maximum error of 4% in the estimated average temperature, according to Smith *et al.* (1968).

Smith *et al.* (1968) observed that the dimensionless location ζ, where the temperature response was identical to the mass average temperature of an object, could be estimated by:

$$\zeta = G^{0.14} - 0.25 \tag{65}$$

Because $G = 1.0$ for a sphere, $\zeta = 0.75$. Smith *et al.* (1968) proposed the following method for estimating the mass average temperature of an irregularly shaped object.

1. Enter G and 1/Bi of an irregularly shaped object into Figure 6 to find $M_1{}^2$ value.
2. Align this $M_1{}^2$ with 1.0 on the geometry index, and find a modified 1/Bi applicable to the sphere.
3. Estimate a mass average temperature from the thermal response at a radial, dimensionless location of 0.75 of a sphere subjected to cooling or heating with a modified Bi found in Step 2.

Since the same $M_1{}^2$ is applicable to the sphere, Equation (63) can be used to estimate the f value. The value of j_{Gs} for the sphere should be estimated by:

$$j_{Gs} = j_c \sin(0.75\,\beta_1)/(0.75\,\beta_1) \tag{66}$$

where β_1 is the first positive root of Equation (67).

$$\text{Bi} = 1 - \beta_1 (\cot \beta_1) \tag{67}$$

and where j_c is the central j value of the sphere.

The estimated j_{Gs} values are shown in Table 5 for selected Bi values.

Example 3. A piece of ham is to be cooled in a 30°F airblast cooler from 160 to 50°F. The overall dimension of the ham is 0.335 ft by 0.541 ft by 0.915 ft. Estimate the cooling time.

Given property values are: $C = 0.893$ Btu/(lb·°F), $h = 8.45$ Btu/(h·ft²·°F), $k = 0.219$ Btu/(h·ft²·°F), $\rho = 67.4$ lb/ft³.

Solution: Assume that the thermal center is at the geometrical center of the ham. Since the characteristic dimension r is the shortest distance between the thermal center and exposed surface, it is equal to 0.335/2 = 0.167 ft. The overall dimension of cross section for area 1 is 0.335 ft by 0.541 ft. Assume that this cross section consists of two half circles of 0.335 ft diameters and of a 0.335 ft by (0.541 − 0.335 ft) rectangle. Therefore:

$$\text{area 1} = 2 \times 0.167^2\,\pi/2 + (0.541 - 0.335)\,0.335 = 0.157 \text{ ft}^2$$

The cross section for area 2 is orthogonal to that of area 1. Therefore, the overall dimension of this cross section is 0.335 ft by 0.915 ft. Similarly, it can be assumed that:

$$\text{area 2} = 2 \times 0.167^2\pi/2 + (0.915 - 0.335)\,0.335 = 0.282 \text{ ft}^2$$

Therefore, from Equation (63), $A_1 = 0.157/(0.167^2\pi) = 1.79$ and $A_2 = 0.282/(0.167^2\pi) = 3.21$. By using Equation (61):

$$G = 1/4 + 3/(8 \times 1.79^2) + 3/(8 \times 3.21^2) = 0.403$$

The reciprocal of Bi is: $0.219/(8.45 \times 0.167) = 0.155$. From Figure 6: $M_1{}^2 = 3.0$. From the definition of thermal diffusivity:

$$\alpha = 0.219/(0.893 \times 67.4) = 0.00364 \text{ ft}^2/\text{h}$$

From Equations (63) and (64):

$$f = 2.303 \times 0.167^2/(3.0 \times 0.00364) = 5.88 \text{ h}$$

$$j_{Gm} = 0.892 \exp(-0.0388 \times 3.0) = 0.794$$

By using Equation (55):

$$50 - 30 = 0.794\,(160 - 30)\,10^{-\theta/5.88}$$

$$\theta = 4.19 \text{ h}$$

From Equation (50):

$$\theta_v = 0.9 \times 5.88\,(1 - 0.794) = 1.09 \text{ h}$$

The solution is $\theta > \theta_v$.

Smith *et al.* (1968) recommend a second method to solve the same problem. By aligning $G = 1.0$ (sphere) and $M_1{}^2 = 3.0$, 1/Bi = 0.8 or Bi = 1.25. From Table 5: $j_{Gs} = 0.993$.

Since the f value is identical:

$$50 - 30 = 0.9932\,(160 - 30)\,10^{-\theta/5.88}$$

$$\theta = 4.76 \text{ h}$$

From Equation (50), $\theta_v = 0.036$ h. The above estimation is correct; there is less than 15% difference between the two estimated times.

Computerizing the method of Smith *et al.* (1968) is difficult, since Figure 6 is required. Therefore, Hayakawa and Villalobos (1988) obtained the following regression formulas to estimate $M_1{}^2$ values as functions of geometry index G and Biot number Bi.

When Bi = ∞

$$\ln M_1{}^2 = 2.2893825 + 0.35330539\,Y_g - 3.8044156\,Y_g{}^2 - 9.6821811\,Y_g{}^3 - 12.0321827\,Y_g{}^4 - 7.1542411\,Y_g{}^5 - 1.6301018\,Y_g{}^6 \tag{68}$$

where $Y_g = \ln G$.

Table 5 Value of j at Mass Average Temperature Location in Sphere for Selected Biot Numbers

Bi	j_{Gs}	Bi	j_{Gs}	Bi	j_{Gs}	Bi	j_{Gs}	Bi	j_{Gs}

0.07	1.00120	0.7	1.00266	1.7	0.98080	8	0.79915	81	0.62468
0.08	1.00135	0.8	1.00156	1.8	0.97765	9	0.78261	101	0.61989

When Bi $< \infty$

$$\ln M_1^2 = 0.92083090 + 0.83409615\,Y_g - 0.78765739\,Y_b - 0.04821784\,Y_g\,Y_b - 0.0408987\,Y_g^2 - 0.10045526\,Y_b + 0.01521388\,Y_g^3 + 0.00119941\,Y_g\,Y_b^3 + 0.00129982\,Y_b^4 \quad (69)$$

where $Y_g = \ln G$ and $Y_b = \ln (1/\text{Bi})$.

An M_1^2 value estimated by Equations (68) or (69) may be used to estimate f and j_{Gm} values for calculating the mass average temperature of an irregular body by using Equations (63) and (64). Equation (64) may be replaced by more accurate equations [Equations (70) and (71)], since j_{Gm} is equal to a spherical j at dimensionless location 0.75 and a plate $-j$ at dimensionless location 0.57359, according to Equation (65).

$$j_{Gm} = 2 \sin M_1 \cdot \cos (0.57359\,M_1)/(M_1 + \sin M_1 \cos M_1) \quad \text{when } 0.01 \leqslant M_1^2 \leqslant 0.03 \quad (70)$$

$$j_{Gm} = \frac{2 (\sin M_1 - M_1 \cos M_1) \sin (0.75\,M_1)}{0.75\,M_1\,(M_1 - \sin M_1 \cos M_1)} \quad \text{when } 0.03 \leqslant M_1^2 \quad (71)$$

M_1, the square root of M_1^2, should be used in Equations (70) and (71).

Surface heat conductances applicable to the two sides of an infinite slab can be different from each other. Uno and Hayakawa's charts (Uno and Hayakawa 1979) determine the location of thermal center and f and j values for these cases.

All of the methods described above are applicable only when the temperature of heat exchange medium is constant. Uno and Hayakawa (1979) estimate the temperatures of food exposed to time variable medium temperatures when its f and j values are known.

SAMPLE PROBLEMS FOR ESTIMATING FREEZING TIME

To provide better understanding of these procedures, four sample problems are presented. The first three show combined application of Cleland and Earle's procedure (1979) and empirical formulas for estimating the thermophysical properties of food. The fourth shows the application of the procedure developed by Hayakawa *et al.* (1983).

Example 4. Spherical carp fish balls 0.1 ft diameter are to be frozen in an IQF airblast freezer. The initial temperature of the balls is 62.7 °F. The freezer air temperature is −12.9 °F, and the coefficient of surface heat transfer is 12 Btu/(h · ft² · °F). Calculate the time required for the center temperature of the fish balls to reach 14.1 °F.

Solution: The thermophysical property values of sample food are estimated first by using the empirical formulas for this estimation. Because no information is available on fat content and other ingredients in the food, its thermophysical properties are approximated with those of lean fish.

The enthalpy can be calculated by integrating Equations (20) and (21), as shown below:

$$\Delta H = \int_{t_f}^{t_o} C\,dt = C_l\,(t_o - t_{sh}) + C_r\,(t_{sh} - t_f) + \frac{E}{n_c - 1}\left[(t_{sw} - t_{sh})^{1-n_c} - (t_{sw} - t_f)^{1-n_c}\right] \quad (72)$$

By assuming that the mass fraction of water in the food is 0.82, the following constants are needed to use the above equation from Table 4:

$$t_{sh} = 30.56;\ C_l = 0.915;\ E = 88.68;\ C_r = 0.447;\ n_c = 1.999$$

The units of the above values are omitted, since they are given in Table 4. From the conditions given in the problem:

$$t_f = 14.1\,°\text{F and } t_{sh} = 30.6\,°\text{F}$$

Because of the definition of t_{sw}:

$$t_{sw} = 32.0\,°\text{F}$$

By substituting these values into Equation (72):

$$\Delta H = 89.2\ \text{Btu/lb}$$

To convert the above enthalpy to the volumetric value, the density of food is estimated by using Equation (19). Since the heat is removed through the frozen layer of food, the density is estimated at t_f. From Table 4:

$$\rho_r = 61.5;\ \rho_l = 66.2;\ S_{ds} = 0.00706$$

Substituting the above values into Equation (19):

$$\rho = 61.9\ \text{lb/ft}^3$$

The volumetric enthalpy is then:

$$\Delta H_v = 89.2 \times 61.9 = 5520\ \text{Btu/ft}^2$$

The specific heat of unfrozen food C_l is 0.915. Since the density of the food ρ_l is 66.2 from Table 4, the volumetric specific heat C_{lv} is:

$$C_{lv} = 0.915 \times 66.2 = 60.57\ \text{Btu/(ft}^3 \cdot °\text{F)}$$

The specific heat of frozen food C_s at t_f is estimated by Equation (21). When the constants given in Table 4 are substituted into this equation, $C_s = 0.836$ Btu/(lb · °F). Since the density at t_f is 61.9 lb/ft³, the volumetric specific heat C_{sv} is 51.7 Btu/(ft³ · °F).

The thermal conductivity of the sample food is approximated by that of codfish, as listed in Table 4. From the table:

$$t_{sh} = 30.56;\ S_{ksx} = 0.00387;\ k_{lx} = 0.302;\ k_{rx} = 0.753$$

The thermal conductivity at t_f is estimated by substituting the above listed values into Equation (24):

$$k_s = 0.782\ \text{Btu/(h} \cdot \text{ft} \cdot °\text{F)}$$

The value of Ste is then determined by using its definition as:

$$\text{Ste} = C_{sv}\,(t_{sh} - t_a)/\Delta H_v = 51.7\,[30.56 - (-12.9)]/5520 = 0.407$$

The value of Pk is calculated also as:

$$\text{Pk} = C_{lv}\,(t_o - t_{sh})/\Delta H_v = 60.57\,(62.7 - 30.56)/5520 = 0.352$$

By using the definition of *Bl*:

$$Bl = hd/k = 12 \times 0.1/0.782 = 1.53$$

where d = fish ball diameter, ft.

For a spherical shape, Plank's constants are $P = 1/16$ and $R = 1/24$. Therefore, using Equations (11), (12), (14), and (15), $P_2 = 0.233$ and $R_2 = 0.0750$. Finally, using Equation (10):

$$\theta_f = \frac{5520}{30.56 - (-12.9)}\left(0.233\,\frac{0.1}{12} + 0.0750\,\frac{0.1^2}{0.782}\right) = 0.368\text{h}$$

Example 5. Whole fish are to be hung on a rack and frozen in an airblast tunnel. The shape of the fish can be approximated by a cylinder 0.165 ft diameter by 0.1 ft long and, for calculation purposes, can be considered an infinite cylinder. The balance of the conditions and thermal properties are the same as in Example 4. As before, calculate the time for the center temperature to reach 14.1 °F.

Solution: All physical property values and dimensionless, parametric values are identical to those estimated in Example 4, except the *Bl* value. Since $d = 0.165$ ft:

$$Bl = 12 \times 0.165/0.782 = 2.53$$

For an infinite cylinder, P and R values are equal to 1/4 and 1/16, respectively. The values of P_2 and R_2 are estimated, as described before, by using Equations (11), (12), (14), and (15), as given below:

$$P_2 = 0.347 \qquad R_2 = 0.103$$

Therefore, by using Equation (10):

$$\theta_f = \frac{5520}{30.6 - (-12.9)}\left(0.359\,\frac{0.165}{12} + 0.103\,\frac{0.165^2}{0.782}\right) = 1.125 \text{ h}$$

Example 6. Packaged lean beef of rectangular brick shape with a thickness of 0.13 ft, a width of 0.39 ft, and a length of 0.52 ft is to be frozen in a blast freezer. The initial temperature of the meat is 44.7 °F, the freezer air temperature is −21.9 °F, and the coefficient of surface heat transfer is 7.04 Btu/(h · ft² · °F). Calculate the time for the average temperature of the package to reach 14.1 °F.

Solution: From the data given in the problem, $t_o = 44.7$ °F; $t_a = 21.9$ °F; $t_f = 14.1$ °F; $h = 7.04$ Btu/(h · ft² · °F).

Assume that the mass fraction of moisture is 0.74. As in Example 4, constants required to estimate the enthalpy or specific heat of lean beef are obtained.

$$t_{sh} = 30.22;\ C_l = 0.834;\ E = 91.13;\ C_r = 0.447;\ n_c = 1.968$$

By using Equation (72), the mass-based enthalpy is obtained:

$$\Delta H = 92.9 \text{ Btu/lb}$$

The following are constants required to estimate the density of food. Use mass fraction of moisture = 0.70 (closest value from Table 4).

$$\rho_r = 63.2;\ \rho_l = 66.8;\ S_{ds} = 0.000194$$

By substituting the above values into Equation (19), the density at 14.1 °F is determined.

$$\rho = 63.56 \text{ lb/ft}^3$$

Therefore, the volumetric enthalpy ΔH_v is:

$$\Delta H_v = \rho\,\Delta H = 5905 \text{ Btu/ft}^3$$

The volumetric specific heat is:

$$c_{lv} = 55.7 \text{ Btu/(ft}^3 \cdot \text{°F)}$$

The value of C_s at t_f is estimated by Equation (21):

$$C_s = 64.07 \text{ Btu/(ft}^3 \cdot \text{°F)}$$

Therefore, the volumetric specific heat C_{sv} is:

$$C_{sv} = 64.07 \text{ Btu/(ft}^3 \cdot \text{°F)}$$

The thermal conductivity at t_f is estimated by Equation (24).

$$k_s = 0.6207 \text{ Btu/(h} \cdot \text{ft} \cdot \text{°F)}$$

The values of Ste and Pk are estimated by using their definitions:

$$\text{Pk} = 0.137 \text{ and Ste} = 0.566$$

The value of *Bl* is 1.48.

Since the shortest side dimension is 0.13 ft, the dimensionless side lengths are: $\beta_1 = 0.52/0.13 = 4$; $\beta_2 = 0.39/0.13 = 3$.

From Figure 1, $P = 0.315$ and $R = 0.089$.

Note that β_1 and β_2 are interchangeable in Figure 1. Therefore, to obtain P, $\beta_1 = 4$ and $\beta_2 = 3$ are entered into the figure. To obtain R, these values of β_1 and β_2 are interchanged. By using Equations (11), (12), (16), and (17), the values of P_2 and R_2 are equal to 0.512 and 0.310, respectively. Finally:

$$\theta_f = \frac{5960}{30.22 - (-21.9)}\left(0.512 \times 0.13/7.04 + \frac{0.310 \times 0.13^2}{0.6207}\right) = 2.04 \text{ h}$$

Example 7. A sample of cherry juice, mass fraction of moisture 0.87, in a 1-ft diameter by 1.5-ft height container is frozen in a −29.2 °F airblast freezer. Estimate the freezing time of the juice. Assume that the freezing completes when the thermal center temperature reaches 14 °F, that the initial temperature of juice is 41 °F, and that the surface overall heat conductances applicable to the top and side surfaces and applicable to the bottom surface are equal to 5.28 and 0.88 Btu/(h · ft² · °F), respectively.

Solution: Table 4 contains the following physical properties—

$t_{sh} = 29.5$ °F	$k_{rx} = 0.993$ Btu/(h · ft · °F)
$\rho_r = 58.9$ lb/ft³	$E = 144.22$ Btu · °F$^{(n_c-2)}$/lb
$C_r = 0.416$ Btu/(lb · °F)	$n_c = 1.896$

Since the radius of the container is 0.5 ft, $r = 0.5$. The values of dimensionless parameters, required to use Equation (36), are estimated by using the definitions given in the Symbols section at the end of the chapter.

$U_o = 0.9375$	$C_{eh} = 152.5$
$U_{sh} = 0.8042$	$U_f = 0.625$
$-U_a = -0.1250$	$1/\text{Bi}_u = 0.3818$
$1/\text{Bi}_n = 2.2907$	$Sf = 3.00$

The values of transformed variables used in Equation (36) are estimated by Equations (37a) and (37b) and the minimum, frequent, and maximum values listed in Table 2. For example, the minimum, frequent, and maximum values of $-U_a$ are:

Minimum: $-0.99902 \times 0.625 + 0.041459 = -0.582929$

Frequent: $-0.87688 \times 0.625 + 0.13828 = -0.40977$

Maximum: 0.8333

By entering these values into Equation (37b):

$$G_2 = 0.610953;\ G_1 = 1.43490;\ G_3 = 2.3009$$

When the above estimated G_1, G_2, and G_3 values are entered with the $-U_a$ value of −0.1250 into Equation (37a), $X_a = 1.2654$.

The estimated values of all transformed variables are:

$X_o = -0.69472$	$X_{eh} = -0.5656$
$X_{sh} = 1.30876$	$X_f = 2.44967$
$X_a = 1.26543$	$X_{iu} = -0.597423$
$X_{in} = 1.8799$	$X_{sf} = 0.687036$

By substituting the above values into Equation (36) $\ln \text{Fo}_f = 1.075$. Since $\text{Fo}_f = \alpha_r t_f / l^2$, estimate α_r:

$$\alpha_r = k_{rx}/(C_r\rho_r) = 0.993/(0.416 \times 58.9) = 0.0405 \text{ ft}^2/\text{h}$$

Therefore:

$$\theta_f = e^{3801} \times 0.5^2/(0.0405 \times 10^{-6}) = 24.54 \text{ h}$$

Approximately 0.75 day is required to freeze the sample.

SYMBOLS

A_1, A_2 = dimensionless cross-sectional areas defined by Eq. (62); used to estimate the geometry index of Smith *et al.* (1968) by Eq. (61)

a = parameter defined by one of Eq. (5)

B = parameter used in Hayakawa's empirical formulas (1983); estimated by Eqs. (48), (51), or (54)

Bi = hr/k; Biot number

Bl = hd/k; used in Eqs. (11) and (44)

Bi_n = dimensionless parameter $h_n r/k_{rx}$, applicable to one side of an infinite rectangular column or one end of a finite cylinder. Symbol r is radius for a cylinder and normally a smaller side dimension for a rectangle in the case of isotropic food. In the case of anisotropic, rectangular food, it is the y-directional side dimension. Note that Bi_n and Bi_u for rectangular food are not Biot numbers, since r is not the shortest dimension between the thermal center and exposed surface of the food. Symbol k_{rx} is a reference k_x normally perpendicular to tissue fibers for a cylinder and parallel to tissue fibers for a rectangle when food is anisotropic.

Bi_n = $h_n d/k$ in Eqs. (40) and (41). For an infinite slab, Bi_n is related to a slab-surface with a lower surface heat conductance h_n.

Bi_u = dimensionless parameter h_r/k_{rx}, applicable to three sides of an infinite rectangular column or to one end and side of a finite cylinder

Bi_u = $h_u d/k$ in Eqs. (39), (40), and (41). For an infinite slab, Bi_u is related to a slab surface with a higher surface heat conductance h_u.

b, b_1 = parameters estimated by Eqs. (4) and (5), respectively

C = specific heat (energy per unit mass per unit temperature difference); if it is affixed with subscript v, it is per unit volume basis

C_{eh} = $E/[C_r (t_{sw} - t_{sh})^{n_c - 1}]$

D_a = $U_{sw}(U_{sw} - U_{sh})$

D_b = D_a/U_{sw}

d = diameter of sphere or infinite cylinder or whole thickness of infinite slab

E = empirical parameter for estimating apparent specific heat

Fo = Fourier modulus, $\alpha_r \theta/r^2$

Fo_1 = $\alpha_r \theta/d^2$

f = slope index of semilogarithmic temperature history curve

F_{ri} = fraction of ice, mass of ice/total mass of water, in food at $(t_a + t_x)/2$

f_{rw} = fraction of water in food, mass of water/mass of food

G = Smith *et al.* (1968) geometry index; see Eq. (61)

G_1, G_2, G_3 = constants estimated by Eq. (37b); used to transform a dimensionless parameter to a corresponding design variable; see Eq. (37a)

h = coefficient of convective surface heat transfer

H = enthalpy of food

j = intercept coefficient of semilogarithmic temperature history curve of food

k = thermal conductivity of food

k_{lx} = thermal conductivity of unfrozen food in x-direction at t_{sh}

k_{ly} = thermal conductivity of unfrozen food in y-direction at t_{sh}

L = latent heat of freezing

Ld = $L/[C(t_{fp} - t_a)]$

L_{kx} = $M_{kx}\, U_{sh}$

L_w = latent heat of freezing of water

Md = $S_{ds}(t_{or} - t_{ar})/\rho_r$

M_{kx} = $S_{ksx}(t_{sh} - t_{ar})/k_{rx}$

M_{klx} = $S_{klx}(t_{or} - t_{ar})/k_{rx}$

M_{kly} = $S_{kly}(t_{or} - t_{ar})/k_{rx}$

M_1^2 = exponential constant determined by Smith *et al.* (1968) chart

n_c = empirical constant for estimating apparent specific heat of food

P = constant in Plank's formula, Eq. (1)

Pc = dimensionless specific heat, which is the ratio of dimensional specific heat at any temperature and reference specific heat

Pd = dimensionless density, which is the ratio of dimensional density at any temperature and reference density

Pk_x = dimensionless thermal conductivity, which is the ratio of dimensional thermal conductivity at any temperature and the reference thermal conductivity in x-direction; used in Eqs. (31) through (34)

Pk = $C_{lv}(t_o - t_{sh})/\Delta H_v$; Plank number, used in Eqs. (11) and (12)

P_1, P_2 = Cleland and Earle's parameters (1979)

R = Plank's constant; see Eq. (1)

R_c = C_l/C_r

R_d = ρ_l/ρ_r

R_{kx} = $k_{lx}/k_{rx} - 1$

R_{ky} = $k_{ly}/k_{rx} - 1$

R_1, R_2 = Cleland and Earle's parameters (1979)

r = characteristic dimension of food; equal to the shortest distance between the thermal center of food and its exposed surface. For example, r = radius for a sphere or cylinder and r = half thickness of an infinite slab with both surfaces exposed to a heat exchange medium.

S = linear rate of change in thermal conductivity or density of food with change in its temperature.

Sf = shape factor; for rectangular column, it is x-directional side dimension/y-directional side dimension; for cylindrical food, it is height/radius

S_T = $C_l(t_{fp} - t_s)/L$; used in Eq. (5)

Ste = $C_{sv}(t_l - t_a)/\Delta H_v$; Stefan number

t = dimensional temperature

U = $(t - t_{ar})/(t_{or} - t_{ar})$; dimensionless temperature; reference cooling medium temperature t_{ar} and reference initial food temperature t_{or} are equal to $-40°$ and 46.4°F, respectively

u = empirical constant; value is estimated by Eq. (47)

W = equivalent heat transfer dimension

W_1, W_2, W_i = parameters defined by Eq. (44)

X = location of freezing or defrosting front measured from an exposed surface; used in Eqs. (2) through (5); also used as a design variable transformed from a dimensionless parameter in Eqs. (35) and (36)

x = location variable; measured from an exposed surface; used in Eqs. (2) through (5) and Eqs. (38) through (41)

x = location variable; for a finite cylinder, it is the radial directional variable; for a rectangular column, it is the direction of tissue fibers or the direction of a larger thermal conductivity

X_x = variable corresponding to any dimensionless parameter

Y_b = ln (1/Bi)

Y_g = ln G

Y_o = $(t_o - t_{fp})/(t_{fp} - t_a)$

α = thermal diffusivity; α_r is reference thermal diffusivity, equal to $k_r/(C_r \rho)$.

β_1, β_2 = ratio of a side dimension of a brick and its smallest side dimension; β_1 also is the first positive root of Eq. (67)

γ = constant estimated by Eq. (5); in Eqs. (25) and (34), it is the ratio of thermal conductivities in the y and x directions for $t \times t_{sh}$

γ = in Eq. (6b) through (6d), $\gamma = C(t_{fp} - t_a)/L$

δ = variable defined by Eq. (4)

ζ = dimensionless location defined by Eq. (65)

ΔH = enthalpy difference, usually per unit mass basis; however, if it is affixed with subscript v, it is per unit volume basis

Δt = temperature difference

Z = half cooling time

θ = dimensional time

π_x = any dimensionless parameter

ρ = density of food

ρ_w = density of water

ϕ = $(t_o - t_{fp})/(t_{fp} - t_s)$

η_1, η_2, η_3 = parameters defined by Eqs. (6b), (6c), and (6d), respectively

Subscripts

a = surrounding heat exchange medium
ar = reference surrounding medium temperature
c = distance measured from current position of exposed surface [Eqs. (2) through (5)].
c = central position (Figure 3)
c = value related to specific heat [Eqs. (29) and (30)]
d = value related to density [Eqs. (19), (27), and (28)]
eh = value related to C_{eh}
f = final food temperature or freezing time
fp = freezing point when freezing or defrosting completes at one single temperature
frq = frequently observed value
Gm = related to average j value, estimated from geometry index
Gs = related to equivalent, spherical j value
g = distance measured from the original position of exposed surface [Eqs. (2) through (5)]
h = hypothetical
i = summation or multiplication index
in = value related to Bi_n
iu = value related to Bi_u
l = unfrozen
m = average (Figure 4)
k = value related to thermal conductivity [Eqs. (22), (23), and (31) through (34)]
max = maximum value
min = minimum value
o = initial or value related to U_o
r = reference value
s = frozen or surface
sh = value related to initial freezing temperature of food t_{sh}
sw = value related to freezing point of water
sf = value related to Sf
u = per unit volume basis (C_{lv}, C_{sv}, ΔH_v) or length of curvilinear portion of semilogarithmic temperature history curve [Eqs. (45) through (55)]
x, y = values related to x and y directions, respectively
1 = frozen region in case of freezing. Defrosted region in case of defrosting [Eqs. (2) through (5)]
2 = unfrozen region in case of freezing; frozen region in case of defrosting [Eqs. (2) through (5)]

CHAPTER 30

THERMAL PROPERTIES OF FOODS

Commodity Refrigeration Load Data 30.1
Enthalpy, Specific Heat, and Thermal Diffusivity 30.9
Thermal Conductivity 30.12
Surface Heat Transfer Coefficient 30.15

THIS chapter summarizes thermal process (heating, cooling, freezing, and thawing) calculations for foods and food substances. The material will help engineers and designers applying these processes to foods in industry, teaching, and research. The references listed at the end of the chapter give more details on errors, accuracy, and methods for obtaining data.

The variable composition and structure of foods greatly affects their thermal properties. In addition, their chemical and physical (and hence thermal) properties change with time, temperature, and other ambient conditions. If the food is a living commodity, such as a stored fruit or vegetable, it generates heat; uses atmospheric oxygen; and gives off carbon dioxide, water vapor, and other gases. All these processes affect ambient surroundings, quality, and storage life.

The composition of meat (fat, lean, bone, moisture, muscle, bone size and shape, and fiber direction) varies depending on the species, age, feeding, and slaughter and postslaughter conditions of the animal. Above freezing, a temperature change can affect the conductivity caused by changes in the fat; below freezing, the conductivity changes rapidly until nearly all the water is frozen. After thawing and refreezing, or a period of above-freezing storage, the conductivity may change because of water loss and other changes.

COMMODITY REFRIGERATION LOAD DATA

Water content. Although not a thermal property, water content significantly influences all thermal properties. Values of specific heat and latent heat of fusion (Table 1) are calculated directly from the water content.

Values for percent of water content (Table 1) are the average for the commodity. For fruits and vegetables, water content varies with the stage of development or maturity when harvested, cultivar, growing conditions, and amount of moisture lost after harvest. Values normally apply to mature products shortly after harvest. For fresh meat, water content values are for time of slaughter or after the usual aging period. In cured or processed products, water content depends on the particular process or product.

Some foods are hygroscopic (gaining moisture during storage), but most lose water that cannot be recovered. Values for specific heat and latent heat of fusion in Table 1 apply only for the corresponding water content given.

Freezing point. Freezing point values in Table 1 are based on experiments where the product was cooled slowly until freezing occurred. Sensitive temperature indicators, such as thermocouples, were inserted into the product, and a sudden temperature rise, caused by ice formation, indicated the beginning of freezing. For fruits and vegetables, Table 1 lists the highest temperature at which specimens froze; they can be seriously damaged by freezing. For other foods, average freezing temperature is shown, largely because initial freezing temperatures are unavailable. Freezing points of foods vary with composition. All apples in a given lot, for example, do not freeze at the same temperature.

As a food product is frozen, ice crystals form, concentrating the remaining unfrozen portion and lowering the freezing temperature. Foods high in sugar content or packed in high syrup concentrations (*e.g.*, dried fruits) may never be completely frozen—even at frozen food storage temperatures. Also, foods normally low in moisture, (*e.g.*, dried beans and peas) do not freeze at these temperatures.

Specific heat. Siebel's formulas can be used to calculate listed specific heat values for above and below freezing (Siebel 1892):

$$c_p = 0.00800a + 0.200 \quad (1)$$

$$c_p = 0.00300a + 0.200 \quad (2)$$

where c_p is specific heat in Btu/lb·°F; a is percent water content; and 0.200 is an arbitrary base, assumed to represent the specific heat of the solid constituents.

Specific heat is a function of temperature. Siebel's formulas are based on the specific heat of water and ice at 32°F of 1.00 and 0.500 Btu/lb·°F, respectively. Specific heat values in Table 1 are for 32°F. In nonfrozen foods, specific heat becomes slightly lower as temperatures rise from 32 to 68°F. In frozen foods, there is a large change in specific heat as temperatures decrease. For example, frozen beef at −40°F has a specific heat of 0.50 Btu/lb·°F, as compared with 0.24 Btu/lb·°F at −166°F (Dickerson 1968). As stated previously, variability in composition is a major characteristic of food substances; this is true for those constituents, particularly water content, that affect specific heat.

In calculating specific heat of frozen foods, it is assumed that all the water is frozen to ice and that the specific heat involved is that of ice. However, this assumption is not entirely correct. As indicated, freezing of most foods is a gradual process, occurring over a wide temperature range. Specific heat values are subject to error; because freezing may be incomplete, the specimen may not be ice but a mixture of frozen and unfrozen constituents (Dickerson 1968).

Latent heat of fusion. Latent heat of fusion is useful in determining the amount of refrigeration required to freeze a product. As with specific heat, the values listed are subject to error because they do not consider any chemical composition other than water content. They are simply the product of the heat of fusion of water (143.59 Btu/lb) and the water content expressed in decimal form. Their use is limited to practical applications, and these values are subject to some discrepancy, depending on product composition.

The following examples show that errors inherent in calculating heat of fusion of foods are not significantly large.

Example 1. Assume a food of 75% moisture content, initially at 32°F, is cooled to 12°F; latent heat of fusion of water, 143.59 Btu/lb; specific heat of ice, 0.50 Btu/lb·°F; specific heat of water, 1.01 Btu/lb·°F; specific heat of nonaqueous 25% of the food [Equation (2)], 0.200 Btu/lb·°F. Assum-

The preparation of this chapter was assigned to TC 11.9, which is presently inactive.

Table 1 Thermal and Related Properties of Food and Food Materials

[a]Water contents of fruits and vegetables are from Lutz and Hardenburg (1968), except for Jerusalem artichokes; dried beans; and peas, yams, dried apples, figs, peaches, prunes, and raisins; the latter are from Watt and Merrill (1963). Water content of meats, dairy and poultry products, miscellaneous candy, and nuts are also from Watt and Merrill (1963); water content of eggs (yolks, salted) and fish are from ASHRAE (1972, 1974, 1978)

[b]Freezing points of fruits and vegetables are from Whiteman (1957), and average freezing oints of other foods are from ASHRAE (1972, 1974, 1978).

[c]Specific heat was calculated from Siebel's formulas (1892).

[d]Latent heat of fusion was obtained by multiplying water content expressed in decimal form by 144, the heat of fusion of water in Btu/lb.

ing only 90% of the water present freezes, a good assumption for many foods is:

(a) Latent heat of freezing:
$143.59 \times 0.75 \times 0.9$ = 96.92 Btu/lb
(b) Sensible heat to cool the ice:
$(0.75 \times 0.9 \times 0.50) \times 20$ = 6.75 Btu/lb
(c) Sensible heat to cool unfrozen water:
$(0.75 \times 0.1 \times 1.01) \times 20$ = 1.52 Btu/lb
(d) Sensible heat to cool nonaqueous material:
$(0.25 \times 0.200) \times 20$ = 1.00 Btu/lb
Total = 106.19 Btu/lb

Calculated from the freezing of water only, $(0.75 \times 144 = 108.0$ Btu/lb) for an error of 100 (108.0 − 106.19)/106.19 = 1.7%.

Example 2. Assume a food of 50% water content. Calculating as above:

(a) 64.62 Btu/lb
(b) 4.50 Btu/lb
(c) 1.01 Btu/lb
(d) 2.00 Btu/lb
Total 72.13 Btu/lb

Using heat of fusion of water gives only 71.80 Btu/lb for an error of 0.5%. In some foods with low water content, very little water will be frozen at −4°F. This causes a large error if the 90% freezing assumption is maintained.

For computing cooling or freezing loads of frozen products, specific heat below freezing and latent heat of fusion are interdependent and should be used together. For many food products, both freezing and temperature change of frozen material take place simultaneously. This occurs over a temperature range, narrow for foods with low solid matter content, wide for those with high solid matter content (see Enthalpy, Specific Heat, and Thermal Diffusivity section).

In Table 1, no latent heat of fusion values or specific heat values below freezing are given for products so low in moisture that the water in them does not freeze.

Heat of respiration. All living food products respire. In respiration, a sugar, usually glucose, combines with oxygen by a step process involving enzymes. A simplified formula for the process is:

$$C_6H_{12}O_6 + 6O_2 \rightarrow 6CO_2 + 6H_2O + \text{energy (heat and energy of ATP)}$$

[a]Column headings indicate temperatures at which respiration rates were determined, within 2 °F, except where the actual temperatures are given.

[b]The symbol * denotes a chilling temperature. The symbol □ denotes the temperature is borderline, not damaging to some cultivars, if exposure is short.

[c]Rates are for 30 to 60 days and 60 to 120 days storage, the longer storage having the higher rate, except at 32 °F, where they were the same.

[d]Rates are for 30 to 60 days and 120 to 180 days storage, respiration increasing with time only at 59 °F.

[e]Rates are for 30 to 60 days storage.

[f]Rates are for 30 to 60 days and 120 to 180 days storage; rates increased with time at all temperatures as dormancy was lost.

[g]Rates are for 30 to 60 days and 120 to 180 days; rates increased with time at all temperatures.

[h]Shelled peanuts with about 7% moisture. Respiration after 60 h curing was almost negligible, even at 85 °F.

[i]Respiration for freshly dug peanuts, not cured, with about 35 to 40% moisture. During curing, peanuts in the shell were dried to about 5 to 6% moisture, and in roasting are dried further to about 2% moisture.

[j]Harvested 141 days after planting (Morris 1952).

[k]Rates are for 30 to 60 days and 120 to 180 days with rate declining with time at 41 °F but increasing at 59 °F as sprouting started.

[l]Rates are for 30 to 60 days and 120 to 180 days; rates increased with time, especially at 59 °F where sprouting occurred.

[m]Rates are for 1 day after harvest.

The end products are CO_2, H_2, and energy in the forms of heat and adenosine triphosphate (ATP) that the cell uses for growth and development. In most stored plant products, little cell development takes place, and the greater part of respiration energy is in the form of heat, which must be taken into account when cooling and storing these living products.

As in all chemical reactions, temperature is important to the rate of respiration. An 18 °F rise in temperature causes respiration rates to double or triple in the range of about 32 to 86 °F. Higher temperatures usually retard respiration.

Fruits, vegetables, flowers, bulbs, florists' greens, and nursery stock are storage commodities with significant heats of respiration. Dry plant products, such as seeds and nuts, have very low respiration rates. Young, actively growing tissues, such as asparagus, broccoli, and spinach, have high rates, as do immature seeds such as green peas and sweet corn. Fast-developing fruits such as strawberries, raspberries, and blackberries have much higher respiration rates than do fruits that are slow to develop, such as apples, grapes, and citrus fruits (Table 2).

Almost all commodities in Table 2 have a low and a high value for heat of respiration at each temperature. When no range is given, the value is an average for the specified temperature and may be an average of the respiration rates for many days.

Most vegetables, other than root crops, have a high initial rate for the first day or two after harvest. Within a few days, they quickly lower to the equilibrium rate (Ryall and Lipton 1972). Asparagus is a good example of this. The first day, heat of respiration at 32°F is 17,652 Btu/ton·day. Within three days, it is down to 8682, and in 16 days to 6160 (Table 3). Sweet corn in the husk at 32°F produces 11,312 Btu/ton·day the first day, and in four days, decreases to 6772 Btu/ton·day. Onions are an exception; they increase in respiration with time as the bulbs lose dormancy. The same is true with garlic (Table 3).

Fruits are different from most vegetables. Those that do not ripen in storage, such as citrus fruits and grapes, have fairly constant respiration rates. Those that ripen in storage (*e.g.*, apples, peaches, and avocados) increase in respiration rate. If a fruit can be held at 32°F, as most apples can, respiration rarely increases, since no ripening takes place. But if these fruits are held at higher temperatures (50 or 60°F), respiration increases and then decreases (see Apples, Table 3). Soft fruits, such as blueberries, figs, and strawberries, show a decrease in respiration at 32°F with time. If they become infected with decay organisms, however, respiration increases.

To use Table 2, select the lower value when estimating respiration heat at the equilibrium state for storage; use the higher value if calculating the heat load for the first day or two, as for precooling and short-distance transport. If the storage temperature is 32 or 40°F, respiration increase in fruits caused by ripening is slight. In fruits that must be held at 50°F or higher, such as mangos, avocados, or bananas, ripening occurs, and the higher rates should be used. Vegetables that lose dormancy in storage, such as onions, garlic, and cabbage, can increase in heat production after long storage.

Not all variations in respiration heat can be attributed to change in rate with time. Broccoli with many flower heads respires faster than if it is mostly stem tissue. Immature fruits and vegetables usually respire faster than more mature specimens (see Potatoes, Table 2). Usually, early, fast-growing cultivars of fruits and vegetables have higher respiration rates than later, slower-developing types.

To obtain the values in Tables 2 and 3, the heat of respiration was assumed to be derived from glucose oxidation in the reaction given earlier. One mole of glucose (180 lb) is oxidized by six moles of oxygen to produce six moles of CO_2 (264 lb). Glucose oxidation produces 1,214,994 Btu/mol. Therefore, one pound of CO_2 represents:

$$1{,}214{,}994/264 = 4602 \text{ Btu}$$

If substrates other than glucose are oxidized in the respiration process, the heat produced amounts to less when organic acids are the substrate, and considerably more when fats are used.

Transpiration of Fruits and Vegetables

Transpiration of moisture from fresh fruits and vegetables is a mass transfer process in which water vapor moves from the surface of the commodity to the surrounding air. Water, the most abundant constituent of these products, exists as a continuous liquid phase within the fruit or vegetable. Terms used to describe transpiration are defined here.

The *transpiration coefficient* of a fruit or vegetable is the mass of moisture transpired per unit mass of commodity, per unit environmental water vapor pressure deficit per unit time. In some

cases, the transpiration coefficient is expressed per unit surface area of commodity, rather than per unit mass.

Transpiration rate of a fruit or vegetable is the mass of moisture transpired per unit mass of commodity per unit time. This rate is sometimes expressed per unit commodity surface area. The transpiration rate of a commodity varies with environmental conditions, among other factors.

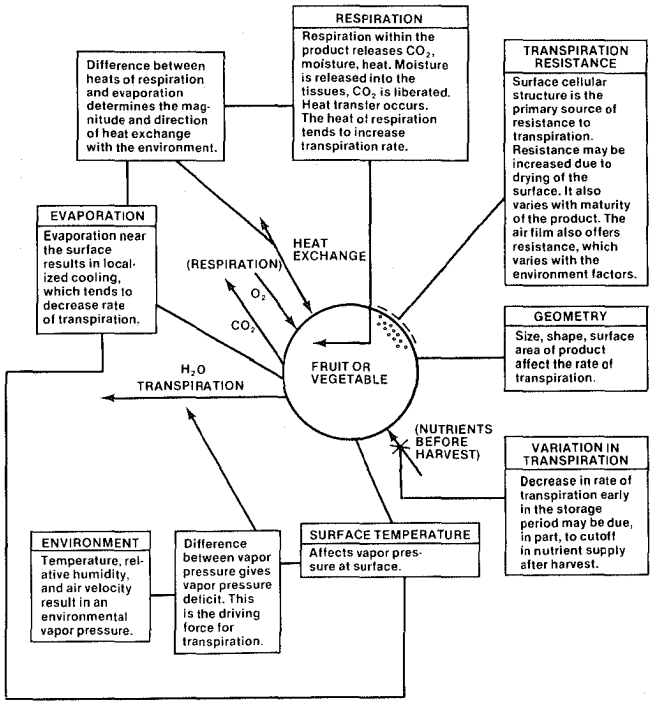
The rate of transpiration in fruits and vegetables affects product quality. Moisture transpires continuously from fruits and vegetables during handling and storage when subjected to a water vapor pressure deficit. Some moisture loss is inevitable and can be tolerated. However, under many conditions, the loss may be sufficient to cause the commodity to shrivel. The resulting loss in mass not only affects appearance, texture, and flavor, but also reduces the salable mass.

All fruits and vegetables do not lose moisture at the same rate when held under the same conditions. Improving present systems to reduce moisture loss from fresh produce maintains the initial harvest time quality longer. The transpiration rate of stored produce must be known to establish the ideal cold storage conditions for fresh fruits and vegetables.

Figure 1 shows some of the factors that affect transpiration rates or transpiration behavior of stored fruits and vegetables and some phenomena associated with transpiration.

Table 4 lists values for the transpiration coefficients of the investigated fruits and vegetables. These values have either been obtained directly or calculated from actual data presented in Sastry *et al.* (1978).

Because of the many factors, the variables involved, and the methods used to obtain the data, not all the values in Table 4 are reliable; they are to be used primarily as a guide or as a comparative indication of transpiration rates among certain commodities obtained from the literature.



RESPIRATION
Respiration within the product releases CO_2, moisture, heat. Moisture is released into the tissues, CO_2 is liberated. Heat transfer occurs. The heat of respiration tends to increase transpiration rate.
Difference between heats of respiration and evaporation determines the magnitude and direction of heat exchange with the environment.
TRANSPIRATION RESISTANCE
Surface cellular structure is the primary source of resistance to transpiration. Resistance may be increased due to drying of the surface. It also varies with maturity of the product. The air film also offers resistance, which varies with the environment factors.
EVAPORATION
Evaporation near the surface results in localized cooling, which tends to decrease rate of transpiration.
HEAT EXCHANGE
(RESPIRATION)
O_2
CO_2
H_2O TRANSPIRATION
FRUIT OR VEGETABLE
GEOMETRY
Size, shape, surface area of product affect the rate of transpiration.
(NUTRIENTS BEFORE HARVEST)
VARIATION IN TRANSPIRATION
Decrease in rate of transpiration early in the storage period may be due, in part, to cutoff in nutrient supply after harvest.
ENVIRONMENT
Temperature, relative humidity, and air velocity result in an environmental vapor pressure.
Difference between vapor pressure gives vapor pressure deficit. This is the driving force for transpiration.
SURFACE TEMPERATURE
Affects vapor pressure at surface.

ENTHALPY, SPECIFIC HEAT, AND THERMAL DIFFUSIVITY

Frozen Foods

The data shown in Table 1 consist of latent heat, freezing point, and specific heat above and below freezing. This table is used to perform refrigeration load calculations by (1) using specific heat above freezing to compute the sensible heat removed during cooling from the starting temperature to freezing point; (2) using latent heat to compute the heat removed during freezing; and (3) using specific heat below freezing to compute the sensible heat removed during cooling from the freezing point to the final frozen storage temperature. This procedure assumes the latent heat of fusion is removed at constant temperature (the freezing point).

Foods do not freeze at constant temperature, however. Beef begins to freeze at about 30 °F, but 25% of the latent heat still must be removed at 25 °F (Riedel 1957). In haddock muscle, some water is bound to proteins and does not freeze at −40 °F (Charm and Moody 1966). In reviewing problems of measuring specific heat and latent heat of foods, Woolrich (1966) noted that fresh beef is not completely frozen at −80 °F, and orange juice is not completely frozen at −139 °F.

The process of food freezing was explained by Staph and Woolrich (1951). When food begins to freeze, the concentration of food solids is increased in the remaining unfrozen water, establishing a lower freezing point for additional phase change. With additional freezing, there is a gradual depression of the freezing point until all freezable water is frozen. Measurement of heat removed during freezing includes both latent and sensible heat. Consequently, the generally accepted criterion of latent heat (change of phase at constant temperature) cannot be rigorously applied to the process of freezing foods (Woolrich 1966). Neither the concept of specific heat nor thermal diffusivity can be applied because there is, as yet, no way to separate the specific heat component from the latent heat component in a food-freezing process.

Table 1 gives conservative results (*i.e.*, the computed refrigeration load is always somewhat greater than that required). The error diminishes for lower frozen storage temperatures. Conversely, if the product is to be cooled only slightly below the initial freezing temperature, using Table 1 can produce significant errors because only a small fraction of the latent heat is actually removed from the product. Results from Table 1 assume all latent heat is removed.

When the product is cooled only slightly below the initial freezing temperature, or where greater accuracy is desired for any final frozen storage temperature, the physical quantity employed in frozen food calculations is the total heat content or enthalpy (Woolrich 1966, Mannheim *et al.* 1955, Short and Staph 1951, Bartlett 1944). This approach has the additional advantage of yielding estimates of percent of water unfrozen.

When enthalpy is tabulated as a function of temperature, a base temperature must be identified. This base is the temperature at which enthalpy is arbitrarily designated as zero. In this chapter, zero enthalpy is at −40 °F.

Enthalpy of Meats, Fruits, Vegetables, and Eggs

Enthalpy of some frozen foods and percent (by mass) of unfrozen water in the food is presented in Table 5. The following equation may be used to calculate the heat transferred from the food.

$$Q = W(h_2 - h_1) \tag{3}$$

where

Q = total heat transferred, Btu
W = mass, lb
h = enthalpy, Btu/lb

Example 3. A quantity of beef (300 lb) is to be frozen to a temperature of −5 °F. Initial temperature of the beef is 50 °F, and moisture content is 74.5%. How much heat must be removed, and what is the total mass of unfrozen water at −5 °F?

Solution: The heat removed in cooling from 50 to 32 °F is calculated from temperatures and specific heat c_p. From Table 5, specific heat is 0.84 Btu/lb · °F, so from 50 to 32 °F:

$$Q = 300 \times 0.84\,(50 - 32) = 4536 \text{ Btu}$$

From Table 5:

$$h_2 \text{ at } 32\,^\circ\text{F} = 131 \text{ Btu/lb}; \; h_1 \text{ at } -5\,^\circ\text{F} = 18 \text{ Btu/lb}$$

Therefore, from 32 °F to −5 °F:

$$Q = W(h_2 - h_1) = 300\,(131 - 18) = 33{,}900 \text{ lb}$$

The total heat to be removed is:

$$Q_{total} = 4536 + 33{,}900 = 38{,}436 \text{ Btu}$$

The amount of unfrozen water at −5 °F is taken from Table 5 as 12%. The total mass of unfrozen water is:

$$300 \times 0.745 \times 0.12 = 27 \text{ lb}$$

Reidel (1957) developed graphs of enthalpy versus water content and percent water frozen versus temperature in beef. Dickerson (1968) combined these two graphs (Figure 2). Below −40 °F, beef is nearly frozen, and the specific heat values shown in Table 6 (Moline *et al.* 1961) may be used for calculations.

Working with twelve fruit juices, Riedel (1951) showed that enthalpy values for fruit juices are represented by Figure 3 within about 2%.

The effect of soluble solids in the juice on the temperature range over which latent heat is removed is apparent in Figure 3. For example, a vertical line at a water content of 95% shows the heat to be removed during freezing. For this high water content, freezing starts at a temperature close to 32 °F, and the main part

[a]Above −40 °F. Adapted from Dickerson (1968) and Riedel (1951, 1956, 1957, 1959).
[b]Temperature range limited to 32 to 68 °F for meats, and 68 to 104 °F for egg yolk.
[c]Total mass of unfrozen water = (Total mass of food) (% water content/100) (% water unfrozen/100).
[d]Calculated for a mass composition of 58% white (86.5% water) and 32% yolk (50% water).
[e]Data for chicken, veal, and venison nearly matched the data for beef of the same water content (Riedel 1957).

Table 6 Specific Heat of Beef

Product	Temperature, °F	Specific Heat, Btu/lb · °F
Beef, Chuck	− 40	0.49
	− 60	0.44
	−110	0.35
	−170	0.24

From Moline *et al.* (1961).

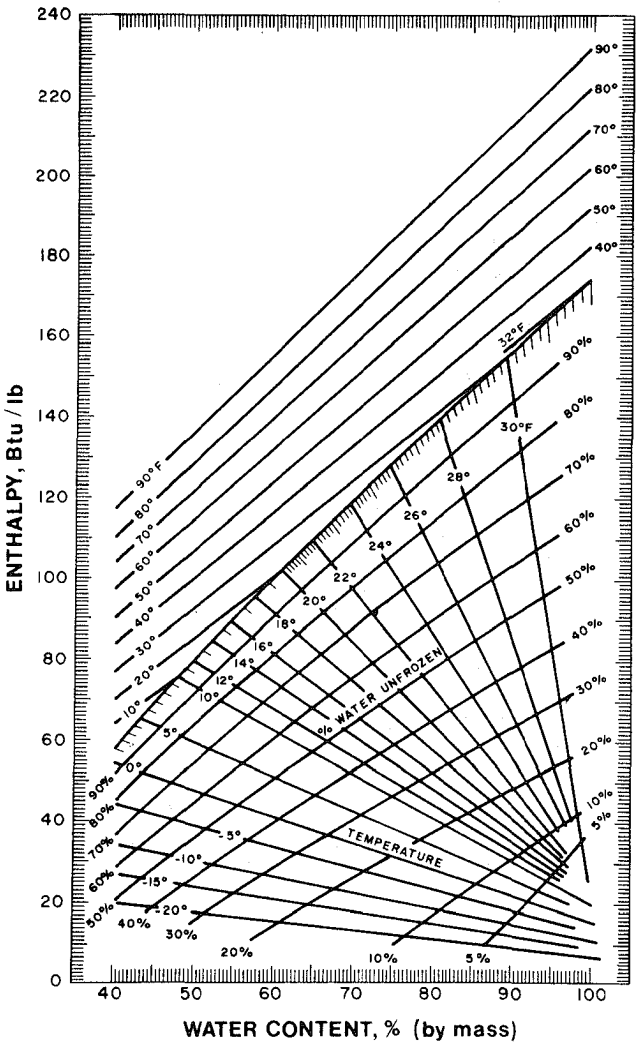

Fig. 3 Enthalpy of Fruit Juices and Vegetable Juices
(Adapted from Riedel 1957)

of the freezing process occurs over a narrow temperature range. Conversely, for 60% water content, freezing starts at a much lower temperature, and appreciable freezing occurs over a greater temperature range due to the lower water content; however, the energy associated with freezing is significantly less.

Figure 3 does not give enthalpy of whole fruits and vegetables because of the effect of solids (fibers, rind, membranes, stems, and seeds) that are not a part of the juice and do not participate in the change of phase. From data collected on 16 fruits and vegetables, Riedel (1951) made the following correlation between enthalpy of fruits and vegetables, enthalpy of juice (Figure 3), and percent solids-not-juice (solids other than those present in the juice).

$$\Delta h = (1 - X_{snj}/100)\,\Delta h_j + 0.29(X_{snj}/100)\,\Delta t \qquad (4)$$

where

Δh = enthalpy difference, Btu/lb
X_{snj} = solids-not-juice, percent by mass
Δh_j = enthalpy difference of juice from Figure 3, Btu/lb
Δt = temperature difference, °F

Equation (4) and Figure 3 have been used to calculate enthalpy of the fruits and vegetables investigated, with the results shown in Table 5. Except for plums and onions, enthalpy of fruits and vegetables (Table 5) differs from Riedel's measured values by less than 5% of enthalpy at 32 °F. Maximum deviation for plums and onions is 12%.

Using measured enthalpy values for egg white, yolk, and shell, Riedel (1957) calculated enthalpy of whole egg with shell. These calculated values are shown in Table 5. Also in Table 5 are enthalpy values of frozen egg products.

Fresh Foods

Specific heat. Above freezing, specific heat can be used instead of enthalpy. Specific heat of fruits, vegetables, juices, meats, breads, and eggs is shown in Table 5; selected data are shown as a function of water content in Figure 4. For juices, variation of specific heat with water content is uniform (Figure 4) and closely matches the equation:

$$c_p = 0.40 + 0.006\,[\%\ \text{water (mass)}] \qquad (5)$$

where c_p = specific heat at constant pressure, Btu/lb · °F.

When data are needed for juices not in Figure 4, Equation (5) yields reasonably accurate specific heat values.

For other foods, the correlation with Equation (5) is not as precise due to the distorting effects of the solids-not-juice content (fats, fibers, rind, membranes, stems, and seeds). However, deviations are not great and, when data are lacking, Equation (5) can be used to estimate specific heat.

Data for meats (Figure 4) were obtained in the temperature range of 32 to 68 °F; caution is recommended in extrapolating the data into the range of 68 to 120 °F, particularly for meats with high fat content. For beef fat, the change in enthalpy from 69 to 120 °F is more than double the change in sensible heat due to specific heat alone (Riedel 1955); the additional heat is required to melt the fat.

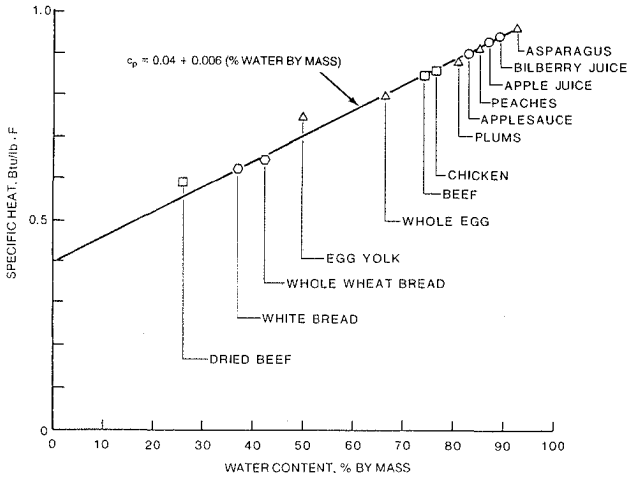

Fig. 4 Specific Heat of Food in Temperature Range of 40 to 90 °F (32 to 68 °F for Meats, 68 to 104 °F for Egg Yolk)

At temperatures between −40 and 32°F, the specific heat of beef fat is constant at 0.40 Btu/lb·°F (Riedel 1955). Above 120°F, it is constant at 0.43 Btu/lb·°F. Between 32 and 120°F, the energy required for a unit change in temperature is highly variable, because
beef fat components change state at different temperatures. Similar data are available for 26 other fats and oils (Riedel 1955).

For similar reasons, the data for egg yolk should not be extrapolated into the temperature range of 32 to 68°F. Riedel (1957) gave data for egg yolk in this temperature range.

Thermal diffusivity. For nonsteady-state heat transfer, the important property is thermal diffusivity α defined by the Fourier equation:

$$\delta t/\delta \tau = \alpha [(\delta^2 t/\delta x^2) + (\delta^2 t/\delta y^2) + (\delta^2 t/\delta z^2)] \quad (6)$$

where

x, y, z = rectangular coordinates, ft
t = temperature, °F
τ = time, h
α = thermal diffusivity, ft²/h

Equation (6) has been solved for numerous conditions and graphical solutions are available (Heisler 1947, Schneider 1963, Smith *et al.* 1967, 1968, Dickerson 1972). Use of Equation (6), however, is limited to temperatures above freezing; and, from a mathematically rigorous point of view, it is restricted to homogeneous, isotropic substances. Generally, foods are nonhomogeneous and anisotropic; however, Equation (6) has been used to find the thermal behavior of foods (Smith *et al.* 1968, Dickerson 1972, Gane 1936, Slavicek *et al.* 1962).

Thermal diffusivity can also be defined as:

$$\alpha = k/\rho c_p \quad (7)$$

where

α = thermal diffusivity, ft²/h
k = thermal conductivity, Btu/h·ft·°F
ρ = density, lb/ft³
c_p = specific heat at constant pressure, Btu/lb·°F

The denominator on the right-hand side of Equation (7) denotes heat absorbing ability; the numerator represents the ability of the material to conduct heat through itself. Schneider (1955) interpreted thermal diffusivity in terms of heating time:

In a transient heating process the thermal capacity of the conducting material dictates the quantity of heat absorbed and the thermal conductivity of the conducting material sets the rate of this heat addition. The reciprocal of the diffusivity, $1/\alpha$ = h/ft², is a measure of the time required to heat this material to some required temperature level and evidently this time is directly proportional to the square of the conducting path length.

Thermal diffusivity data for foods are scarce; but reasonable estimates can be obtained from Equation (7), using values of thermal conductivity, specific heat, and density. A few experimental values are available (Table 7). Like other thermal properties of foods, thermal diffusivity strongly depends on water content, as shown by Riedel's correlation (Reidel 1969):

$$\alpha = 0.00341 + (\alpha_w - 0.00341)[\%\text{ water (mass)}/100] \quad (8)$$

where

α = thermal diffusivity, ft²/h
α_w = thermal diffusivity of water at desired temperature, ft²/h

When data are lacking, Equation (8) can be used to estimate thermal diffusivity of foods, but its use must be limited to water contents above 40% by mass. For water contents below 40%, there is some question whether the water represents the continuous phase. If another constituent (such as fat—usually a dispersed phase) replaces the water as the continuous phase, there would be an abrupt drop in thermal conductivity and thermal diffusivity.

Meats. Equation (8) applies to foods with variable amounts of water, fat, and fiber; if the water content is reduced, it is assumed that the water is replaced with fat. Consequently, the thermal diffusivity of 0.00341 ft²/h, obtained from Equation (8) for zero water content, is reasonably close to a computed value for fat [from Equation (7)]. Therefore, Equation (8) is applicable only where a reduction in water content is compensated for by an increase in fat content. Equation (8) cannot, for example, be used for freeze-dried samples, where a reduction in water content is compensated for by an increase in air content.

When meat samples are heated to temperatures in the range of 100 to 150°F, juices sometimes exude. Heat transfer rates can be altered significantly, depending on whether the exuded juices remain in the sample and contribute to heat transfer, or drain away from the meat and lower thermal conductivity. The data in Table 7 for the range of 100 to 150°F applies only where juices remain in the meat sample.

Fruits. Most data for fruits (Table 7) apply to the flesh of the fruit; for products such as apples, cherries, and peaches, the data can be used for the whole fruit (with rind) because a very thin rind neither improves nor inhibits heat transfer.

Conversely, the relatively thick rind of grapefruits, oranges, and lemons has a pronounced effect on heat transfer rates, even though thermal diffusivity of the rind is about the same as that of the juice vesicle (Bennett *et al.* 1970). Although it may seem that these equal thermal diffusivities should result in equal heat transfer rates through both components, the problem arises because the thermal conductivity of the rind is only half that of the juice vesicle (Bennett *et al.* 1964). The rind has a spongy layer of loosely arranged cells with many gas-filled intercellular spaces, producing an insulating effect. Because of these spaces, the rind density is only 0.5 that of the juice vesicle (Bennett *et al.* 1970). The lower density compensates for the lower thermal conductivity, leaving thermal diffusivity essentially unchanged [Equation (7)].

Food Container Materials

In calculating heat transfer in foods, it may be necessary to consider the effect of the food container. Thermal properties of some food container materials are given in Table 8; the data for plastics apply only for monolayer materials and not for plastic laminates. Thin plastic films can have a thermal resistance much greater than indicated by their thermal conductivities is because of imperfect contact between laminated films and gas bubble buildup on the hydrophobic surface of the plastic.

In much the same way as a thick rind insulates the flesh of fruit, a food container may insulate food. Thermal diffusivities and conductivities of glass and stainless steel are greater than those of foods (Tables 7 and 9). Consequently, these two materials do not delay heat transfer in foods. However, if there is no intimate contact between the food and the container, the resulting void space adds resistance to heat transfer that may be greater than the resistance caused by the container.

THERMAL CONDUCTIVITY

Heat conduction (as opposed to convection and radiation) can be described as the transfer of heat associated with motion of the particles (molecules, atoms, electrons) of a substance without appreciable displacement or flow of those particles. This mode of heat transfer depends on a property of substances called the *coefficient of thermal conductivity*, which is the quantity of heat that flows in unit time through a plate of unit thickness and unit area with unit temperature difference between its faces.

BUTTERFAT IN MIXTURE, % VOLUME

Fig. 5 Thermal Conductivity of Gelatin Gel [6% (mass)]—Butter Fat Mixtures at 39 °F

Thermal conductivity depends on many factors, including the kind of substance (metal, dielectric, crystalline, amorphous, solid, liquid, gas); composition (impurities, mixtures); structure and structural orientation; temperature; and pressure. Thus, accurate measurement and prediction of thermal conductivity may be difficult for many foods, although a large amount of experimental data are available and estimations or predictions sufficiently accurate for practical purposes can be made for many food materials.

Thermal Conductivity of Mixtures

Thermal conductivity for mixtures of 6% gelatin gel and butter fat arranged in several ways are shown in Figure 5, which was adapted from a more detailed study done by Lentz (1961). Since the ratio of thermal conductivities of butter fat and 6% gelatin gel is roughly the same as for fat and lean portions of meat, the curves indicate the variability to be expected in the thermal conductivity of meat. Conductivity is maximum for layers arranged parallel to the direction of heat flow (Curve A) and minimum for perpendicular layers (Curve D); other arrangements fall in between. Curves B (calculated) and C (experimental) give values for small spherical butter fat particles dispersed in the gel. The calculated curve was obtained using Eucken's adaptation (Eucken 1940) of Maxwell's equation (Maxwell 1904) for conductivity of a mixture composed of small spheres of one substance dispersed in another:

$$k = k_c \frac{1 - [1 - a(k_d/k_c)]b}{1 + (a - 1)b} \qquad (9)$$

where

k = conductivity of mixture
k_c = conductivity of continuous phase
k_d = conductivity of dispersed phase
$a = 3k_c/(2k_c + k_d)$
$b = V_d/(V_c + V_d)$
V_d = volume of dispersed phase
V_c = volume of continuous phase

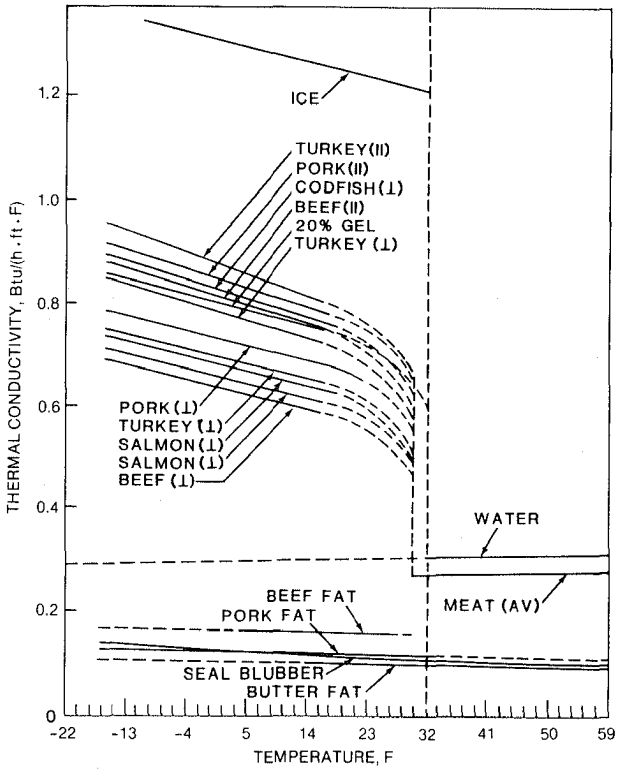
The derivation of this equation assumes the dispersed particles are sufficiently separated for their effects in disturbing heat flow to be independent of each other. The units in Equation (9) can be any units as long as the thermal conductivity units are all the same and the volume units are all the same.

Effect of Temperature

Temperature effects on thermal conductivity of a number of meats and fats, as well as gelatin gel and ice, in the range of −13 to 50 °F are shown in Figure 6 (see Table 9 for the composition of sample materials), adapted from Lentz (1961). Rapid change of phase and the possibility of subcooling and metastable states make values in the 14 to 32 °F range more difficult to measure and less reliable than at other temperatures. The effect of meat fiber or structural orientation in the frozen state appears to be 10 to 20%. Thermal conductivity of fats is affected only slightly by temperature in the range studied.

Thermal Conductivity and Water Content

Figure 7 shows the relation between thermal conductivity and moisture content for a wide range of food materials, based on a study using the Maxwell-Eucken equation (Van den Berg and Lentz 1975). The effect of temperature is also included. The curves represent data on sugar solutions and fruit juices (Riedel 1949), milk and evaporated milk (Leidenfrost 1959), butter fat and gelatin gels (Lentz 1961), fats (Lentz 1961, Cherneeva 1956), and meats (Lentz 1961, Cherneeva 1956, Hill *et al.* 1967, Miller and Sutherland 1963), with an accuracy of ±10% if an allowance of ±7%



‖ indicates heat flow parallel to fiber structure
⊥ indicates heat flow perpendicular to fiber structure

Fig. 6 Thermal Conductivity of Meats, Fats, Gelatin Gel, and Water between −13 and 50 °F

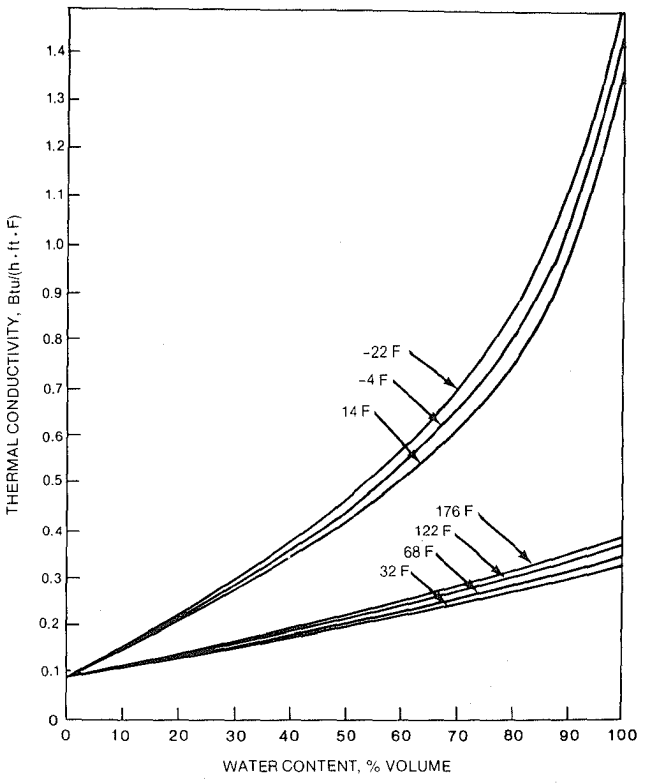


Fig. 7 Effect of Water Content and Temperature on Thermal Conductivity of Food Materials

is made for fiber direction in frozen meats. The allowance is positive for heat flow parallel to the fiber structure; negative for flow across the structure.

The study on which Figure 7 is based differs from studies done by Lentz (1961), Riedel (1949), Leidenfrost (1959), Spells (1960-61), and Sweat (1974), in that water content was calculated on a volumetric rather than gravimetric basis, and a wider range of food materials and temperatures is covered. In addition, only materials not containing appreciable air were included. For the above-freezing temperatures, the curves follow the Maxwell-Eucken equation, assuming water to be the continuous phase, and the nonaqueous part the dispersed phase. For below-freezing temperatures, the curves best fitting the experimental data (Figure 7) represent an average of the results calculated, assuming that ice is the dispersed phase in one instance and the nonaqueous part, plus unfrozen water, is the dispersed phase in the other instance.

The Maxwell-Eucken equation predicts thermal conductivity from water content, even though the assumptions on which it is based do not appear to be closely met, because:

1. The thermal conductivity of water is high compared to that of the nonaqueous components, especially at below-freezing temperatures.

2. The thermal conductivity of the nonaqueous components falls within a relatively narrow range—most organic substances between 0.081 to 0.12 Btu/h·ft·°F with most fats in the 0.092 to 0.10 range.

3. The mass densities of fats, proteins, and carbohydrates fall within narrow ranges that are relatively close together [values used in the study were 57.5, 84.4, and 96.9 lb/ft^3 for fat, protein, and carbohydrate, respectively (Van den Berg and Lentz 1975)].

Tabular Data

Table 9 lists thermal conductivities for many foods (Qashou *et al.* 1972). Data in the table have been averaged, interpolated, extrapolated, selected, or rounded off from the original research data. Tables 7 and 9 also include ASHRAE research data on low and intermediate moisture foods (Sweat 1985).

SURFACE HEAT TRANSFER COEFFICIENT

The surface heat transfer coefficient, while not a thermal property of a food or any other material, is needed to design heat transfer equipment for foods where convection is involved. Newton's cooling law in one dimension defines it as

$$q = h(t_s - \theta_\infty) = -k\left(\frac{\partial t}{\partial \mathbf{n}}\right), \text{ for time} > 0 \qquad (10)$$

where

q = heat flux
h = heat transfer coefficient
t_s = surface temperature
t_∞ = ambient temperature
k = thermal conductivity
$\mathbf{n}$ = normal surface vector

Using a linear boundary condition helped mathematicians solve the heat conduction equations but required h to be determined by experiments. Some efforts have theoretically determined h for simple geometries and laminar flow by solving the Navier-Stokes energy and continuity equations simultaneously.

The results showed that factors affecting the surface heat transfer coefficient are not within the object being cooled, frozen, or thawed, but are related to the boundary layer that forms outside the body. This boundary layer is affected by the dynamics of the surrounding fluids and the conditions at the surface of the body. Surface roughness, packaging, etc., influence the flow regime around the body, thus affecting the surface heat transfer coefficient.

Because the heat transfer coefficient depends on the velocity of the fluid to which heat is transferred, experimenters represent their results in the correlation of the Nusselt number as a function of Reynolds and Prandtl numbers. These Nu-Re correlations predict theoretical values accurately for simple geometries such as flat plates.

Theoretical derivations, as well as laboratory experiments, showed that h is a local phenomenon and not a constant—even in the simplest geometries and flow patterns. The value of h used in the Nu-Re correlations is the area averaged value of the local heat transfer coefficient.

Surface Heat Transfer Coefficient Table

The data were organized in Table 10 to be comprehensive yet compact enough for simple use. The first two columns of the table describe the product or geometrical shape used in the experiment. Columns 3 through 7 describe the experimental conditions used to determine h. Column 8 describes the types of heat transfer present during the experiment. Columns 9 through 12 describe the Nusselt number correlation, the error associated with h, the range of the Reynolds number or other parameter where the correlation was determined, and the value of the surface heat transfer coefficient. The last three columns contain the classification, the reference, and comments. An explanation of each column follows.

1. *Product.* The product name is entered in alphabetical order.
2. *Shape and characteristic length.* The shape assumed for the calculation of h is given; otherwise, it is the characteristic

[a]The symbol ⊥ indicates heat flow perpendicular to the grain or structure; the symbol = indicates heat flow parallel to the grain of structure.

[b]The symbol k is used for thermal conductivity.

[c]The rating *A* indicates data considered reliable by reviewers from TC 11.9, within practical limits. The rating *I* indicates data that appears to be reliable within practical limits, but for which background information supplied (*e.g.*, composition factors or conditions of measurement) was insufficient for a firm assessment. *U* indicates data unrated because it did not fall within the area of competence of any reviewer of TC 11.9.

[d]References quoted are those on which given data are based, although actual values in this table may have been averaged, interpolated, extrapolated, selected, or rounded off.

[e]This column includes density (d, in lb/ft^3), pressure (P, in psia), fat content (%), and other details.

[a]Characteristic length is used in Reynolds number and illustrated in the Comments column where appropriate.

[b]Experimental methods are coded as follows:
TI—transient; infinite series heat transfer solution is simplified to one term
TB—transient; solution of convection boundary condition assuming uniform product temperature
TC—transient; heat flux quantified using calorimetry
TF—transient; monitoring of heat flux with heat flux meter
TN—transient; heat conduction equation solved numerically
NS—experimental method not specified

[c]Thermocouple wire gage if given; Thermocouple type; T is copper constantan.

[d]FC: forced convection; RAD: radiation effects included; EVAP: evaporation included; NC: natural convection.

[e]Nu = Nusselt number, Re = Reynolds number, Gr = Grashoff number, Pr = Prandtl number

product shape. The characteristic length given is the dimension used to calculate the Nusselt number. If another dimension was used for the Reynolds number, it is shown in the Comments column.

3. *Transfer medium.* The fluid used for forced convection is listed. The correlations that did not include a Prandtl number should be used with fluids similar to the experimental conditions, since significant variations in the calculation of h may be encountered if different fluids are used. If the correlation used the Prandtl number, the use of other transfer media can be accounted for by the correlation when the Prandtl dimensionless number is within the same order of magnitude.
4. *Temperature difference* (Δt) or *temperature of medium.* The surface heat transfer coefficient exhibits a weak dependence on temperature; therefore, for accurate determinations, the temperature of the body and the medium should be known. The user can also compare the experiment with design conditions.
5. *Velocity of medium.* This column lists either the velocity range or the velocity corresponding to the surface heat transfer coefficient. The location at which the velocity was measured is explained in the Comments column.
6. *Experimental method.* Each data set was typified according to the experimental methods used. The methods of estimating the surface heat transfer coefficient fall mainly into three categories: (1) the steady-state measurement of surface temperature for a given heat dissipation of the body, (2) the measurement of the transient temperature as the body cools or heats, and (3) the measurement of heat flux at the surface of the body. The code that indicates the type of experimental method used is explained in the footnotes to the table. For more details, refer to Arce and Sweat (1980).
7. *Temperature measurement.* Size, type, and location of temperature sensors are described. This information can help to evaluate the accuracy and relevancy of the temperature measurements.
8. *Type of heat transfer.* Especially with forced convection cooling, freezing, or heating of agricultural products, two other kinds of heat transfer occur: evaporative cooling and radiative transfer. Evaporative cooling is inherent with any object containing moisture. Radiative cooling is experienced especially by single standing objects cooled in an environment substantially cooler than their surface temperature. Some experimenters corrected their measurements for these types of transfer, but where not corrected, the types included in the correlation are listed in this column.
9. *Nu-Re correlation.* The Nusselt number as a function of Reynolds number, Prandtl number, and any other variables, such as the geometry factor G are listed in this column. All the correlations listed are of the form $Nu = c_1\ Re^{c2}\ Pr^{1/3}$, where the Nusselt number hD/k characterizes the heat transfer and contains the surface heat transfer coeffficient h, the characteristic length D, and the thermal conductivity k, of the fluid at the surface temperature conditions. The Reynolds number $DV\rho/\mu$, characterizes the dynamic properties of the fluid and has the same characteristic dimension D, the velocity of the fluid V, and the density ρ and viscosity μ of the fluid at the average temperature conditions. The Prandtl number

[f]Errors are given as perent of measured value. Correlation coefficients are given as r values

[g]Characteristic length is given in column 2, free stream velocity is used, unless specified otherwise in column 15.

[h]N/A indicates that *hs* was not reported in original article.

[i]The three values in the classification represent the method used to obtain h, the accuracy reported, and the location of the point or Nu-Re correlation relative to the rest of the data obtained. For method used: 0 = not reported, 1 = less accurate, 2 = most accurate methods. For accuracy: 0 = not reported, 1 = less accurate, 2 = most accurate. For comparison with other data: 0 = no comparison possible, 1 = substantially different from other data, and 2 = close to other published data.

$c_p\mu/k$ characterizes the heat transfer properties of the fluid at average temperature conditions.

10. *Error or correlation coefficient.* Measurement errors are estimated in this column. All the entries do not use the same basis; some researchers measured the error as the correlation coefficient of a least squares fit to the experimental data, while others measured it comparing their results to some known correlation or the mean of their experiment. The correlation coefficient r is a relative measurement and should be used to compare only experiments performed under the same conditions; correlation coefficients higher than 0.95 represent a close fit to the experimental data even though smaller values for r may have even better fits to the data for other conditions.
11. *Reynolds number range.* Reynolds numbers indicate the range where the Nusselt-Reynolds correlation is valid, to avoid extrapolation. The range of other variables, if used, is also reported, such as the geometry factor G.
12. *Surface heat transfer coefficient h.* Values obtained in the literature are listed in this column. Whenever possible, all available data were listed, except where an overwhelming amount of data made it impractical. In such a case, a representative sample covering the complete range of experimental conditions has been included. The surface heat transfer coefficients are listed in Btu/h·ft²·°F. The values for h include other types of heat transfer, such as evaporative cooling, which are listed in separate columns. For each h reported in this column, there should be a corresponding set of values for velocity, characteristic length, and temperature at which the h value was obtained. The table leaves blanks below values in some columns, meaning that the value of h is calculated keeping that variable constant.
13. *Classification.* Classification of the data obtained from the references is listed to help the designer choose an accurate value for the surface heat transfer coefficient. The figures compare the theoretical method used, accuracy, and overall placement of the results relative to the rest of the data reported. Therefore, three values were needed: (a) for the theoretical methods used, (b) for the relative accuracy, and (c) for the agreement with the rest of the data reported.
    (a) *Theoretical method.* This value shows the inherent accuracy of the method used to calculate h. For instance, a value for h calculated using the truncated infinite series solution should be more accurate than one calculated using some type of calorimetric determination. This classification does not evaluate the experimental setup nor the analysis of the data. The number 2 indicates that the method used was of higher accuracy than for 1, and 0 indicates that the method used was not reported.
    (b) *Relative error.* The error was evaluated qualitatively with the following parameters: the error reported (either as a correlation coefficient, a standard deviation, or a percentage deviation from the mean); the number of data points per log cycle of Reynolds numbers; and any other indication of accuracy available such as actual measurements of an assumed constant. The cutoff points between 1 and 2 were 0.8 for the correlation coefficient, an error of 40% or larger for the experiment, or five or less data points per cycle of Nu-Re correlation

reported. The number 2 indicates the most accuracy, 1 indicates less accuracy, and 0 indicates no error data.

(c) *General agreement of the data.* The Nu-Re correlations were plotted, and the relative location of the curves was noted for the classification. The slope of the curve was emphasized more than its location in the plane, since Reynolds numbers may have been calculated using different values of velocity and characteristic length, depending on where these were measured. The number 2 indicates the closest agreement with other similar data, 1 indicates less agreement with other data, and 0 indicates that the data were not plotted; therefore, no comparison could be made.

14. *Reference.* The article from which the data was obtained is listed.
15. *Comments.* This column lists any additional information.

How to Use Tables

Users should obtain h values from the Nu-Re correlations in the tables, where available, rather than selecting h values directly from column 12. The h values are applicable only for one set of experimental conditions, whereas the Nu-Re correlations are more generally applicable. The design conditions may vary from the experimental conditions in the article, provided the Reynolds number is within the same range.

The amount of data in the tables is limited when the almost infinite number of products, product form and shape, packaging condition, and process condition are considered. Therefore, the Nu-Re correlations have much greater utility in estimating h values. Techniques for dealing with irregular shapes may be used in conjunction with the Nu-Re correlations.

Considering the great variety of geometrical shapes and arrangements possible, some experimenters have attempted to categorize all the shapes with some type of parameter. For instance, Smith *et al.* (1967) use a geometry index G to characterize ellipsoids or shapes simulated by ellipsoids. Only the overall shape is important and any agricultural product can be approximated with an ellipsoid; therefore, one correlation covers all possible shapes.

The following guidelines are important in choosing the Nu-Re correlation: (1) try to use a Nu-Re correlation for a Reynolds number in the same range as is being designed for; (2) avoid extrapolations; (3) use data for the same heat transfer medium with the temperature and temperature difference similar to the design conditions; and (4) consider the same types of heat transfer that the design includes, *i.e.*, evaporative, radiative, etc. If, after looking at these factors, the choice is narrowed down to a few correlations, use the classification number to decide which one is best. The classification reflects the accuracy and the method used in the experiment.

Once the Nu-Re correlation has been chosen, use the same dimensions and velocities defined in the article. In case of doubt, check to see if the Nusselt number obtained is in the range of the experiment. If there are still doubts, consult the original source. Since the Nu-Re correlations are logarithmic, any small errors mean a large change in h. Special emphasis should be given to the use of characteristic lengths and free stream, or interstitial velocity should be emphasized in calculating Reynolds and Nusselt numbers.

If data from column 12 are used, the conditions of the design must equal those in the experimental procedure, since the value of h is valid only for one set of conditions. If all conditions are matched, h values from the table would be the most accurate, since a generalization was made to fit all the data in one Nu-Re correlation. However, if this match is not exact, a Nu-Re correlation should be used to calculate h; data not reported in correlation form can be used to check the estimate.

Many foods not packaged or packaged in permeable materials lose moisture during cooling. The effects of packaging on the value of surface heat transfer coefficient are not well documented.

CHAPTER 31

SPACE AIR DIFFUSION

Terminology 31.1
Methods of Room Air Distribution 31.1
Methods of Evaluation 31.5
Principles of Room Air Distribution 31.8
System Factors 31.12
System Design 31.13

TERMINOLOGY

THE following definitions refer to air diffusion equipment and methods.

Aspect ratio The ratio of length to width of an opening or core of a grille.

Axial flow jet A stream of air whose motion is approximately symmetrical along a line, although some spreading and drop or rise can occur from diffusion and buoyancy effects.

Coefficient of discharge Ratio of area at vena contracta to area of opening.

Core area The total plane area of that portion of a grille, included within lines tangent to the outer edges of the outer openings through which air can pass.

Damper A device used to vary the volume of air passing through a confined cross section by varying the cross-sectional area.

Diffuser An outlet discharging supply air in various directions and planes.

Diffusion Distribution of air within a space by an outlet discharging supply air in various directions and planes.

Drop The vertical distance that the lower edge of the horizontally projected airstream drops between the outlet and the end of its throw.

Effective area The net area of an outlet or inlet device through which air can pass, equal to the free area times the coefficient of discharge.

Entrainment The movement of room air into the jet caused by the airstream discharged from the outlet (secondary air motion).

Entrainment ratio The total air divided by the air discharged from the outlet.

Envelope The outer boundary of an airstream moving at a perceptible velocity.

Exhaust opening or inlet Any opening through which air is removed from a space.

Free area The total minimum area of the openings in the air outlet or inlet through which air can pass.

Grille A covering for any opening through which air passes.

Induction Room air drawn into an outlet by the primary airstream (aspiration).

Isothermal jets Air jets with the same temperature as its surrounding air.

Lower zone Room volume below the stratification level created by displacement ventilation.

Nonisothermal jets Air jets with a initial temperature different from its surrounding air.

Outlet velocity The average velocity of air emerging from the outlet, measured in the plane of the opening.

Primary air The air delivered to the outlet by the supply duct.

Radius of diffusion The horizontal axial distance an airstream travels after leaving an air outlet before the maximum stream velocity is reduced to a specified terminal level, *e.g.*, 200, 150, 100 fpm.

Register A grille equipped with a damper or control valve.

Spread The divergence of the airstream in a horizontal and/or vertical plane after it leaves the outlet.

Supply opening or outlet Any opening through which supply air is delivered into a ventilated space being heated, cooled, humidified, or dehumidified. Supply outlets are classified according to their location in a room as sidewall, ceiling, baseboard, or floor outlets. However, since numerous designs exist, they are more accurately described by their construction features. (See Chapter 17 of the 1992 ASHRAE *Handbook—Systems and Equipment*.)

Temperature differential Temperature difference between primary and room air.

Terminal velocity The maximum airstream velocity at the end of the throw.

Throw The horizontal or vertical axial distance an airstream travels after leaving an air outlet before the maximum stream velocity is reduced to a specified terminal velocity, *e.g.*, 100, 150, 200 fpm. Data for the throw of a jet from various outlets are generally given by each manufacturer for isothermal jet conditions and without boundary walls interfering with the jet.

Total air The mixture of discharged air and entrained air.

Vane A thin plate in the opening of a grille.

Vane ratio The ratio of depth of vane to minimum width between two adjacent vanes.

Upper zone Room volume above the stratification level created by the displacement ventilation.

METHODS OF ROOM AIR DISTRIBUTION

Room air distribution systems can be classified as mixing, displacement, and local systems.

Mixing Systems

Conditioned air is normally supplied to air outlets at velocities much greater than those acceptable in the occupied zone. Conditioned air temperature may be above, below, or equal to the air temperature in the occupied zone, depending on the heating/cooling load. The diffuser jets mix with the ambient room air by entrainment, which reduces the air velocity and equalizes the air temperature. The occupied zone is either ventilated by the decayed air jet directly or by the reverse flow created by the jets.

Mixing air distribution creates relatively uniform air velocity, temperature, humidity, and air quality conditions in the occupied zone.

The preparation of this chapter is assigned to TC 5.3, Room Air Distribution.

Typical outlets and their performance. Straub *et al.* (1956, 1957) classified outlets into five groups:

Group A. Outlets mounted in or near the ceiling that discharge air horizontally.
Group B. Outlets mounted in or near the floor that discharge air vertically in a nonspreading jet.
Group C. Outlets mounted in or near the floor that discharge air in a vertical spreading jet.
Group D. Outlets mounted in or near the floor that discharge air horizontally.
Group E. Outlets mounted in or near the ceiling that project primary air vertically.

Analysis of outlet performance was based on primary air pattern, total air pattern, stagnant air layer, natural convection currents, return air pattern, and room air motion.

Figures 1 through 5 show the room air motion characteristics of the five outlet groups; exterior walls are depicted by heavy lines.

The principles of air diffusion emphasized by these tests are as follows:

1. The primary air (shown by clear envelopes in Figures 1 through 5) from the outlet down to a velocity of about 150 fpm can be treated analytically. The heating or cooling load has a strong effect on the characteristics of the primary air.
2. The total air, shown by diagonally lined envelopes in Figures 1 through 5, is influenced by the primary air and is of relatively high velocity (but less than 150 fpm), with air temperatures generally within 1°F of room temperature. The total air is also influenced by the environment and drops during cooling or rises during heating; it is not subject to precise analytical treatment.
3. Natural convection currents form a stagnant zone from the ceiling down during cooling, and from the floor up during heating. This zone forms below the terminal point of the total air during heating and above the terminal point during cooling.

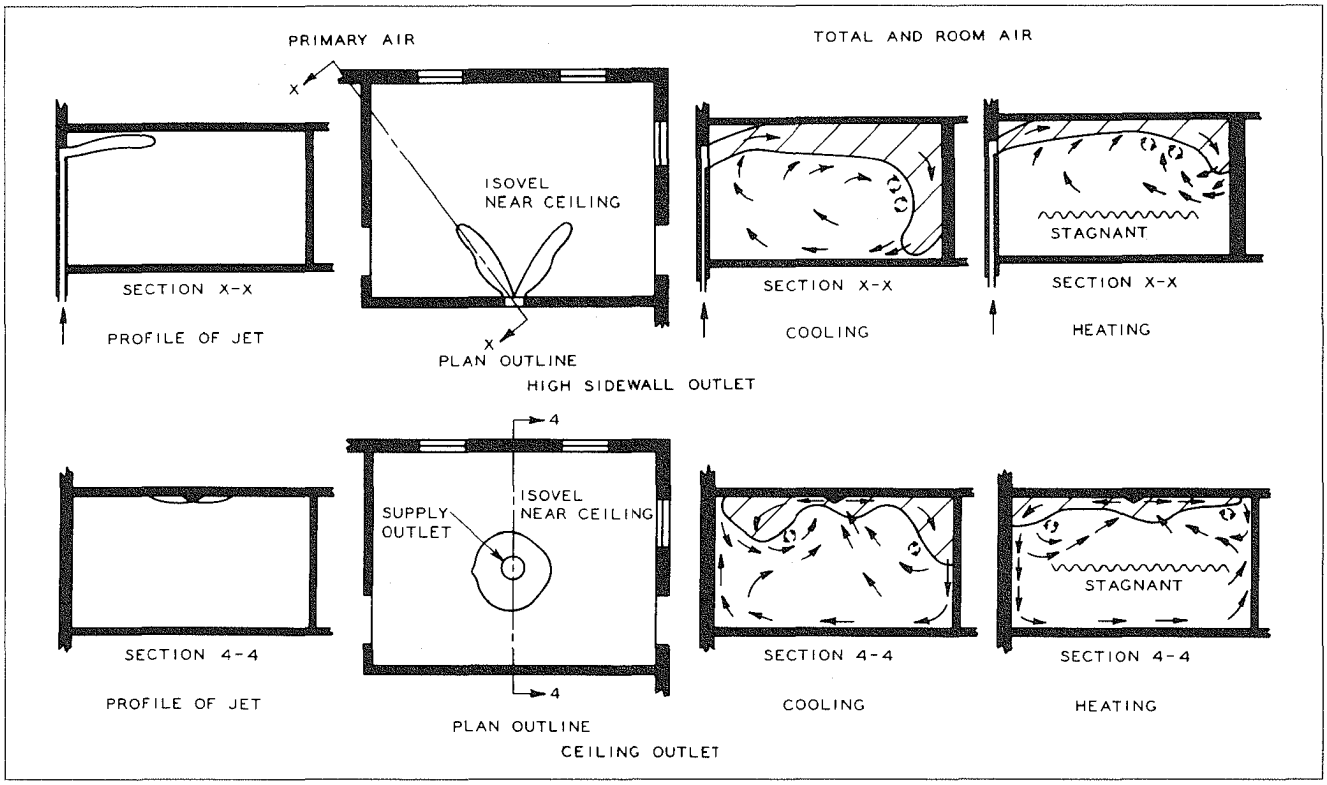

Fig. 1 Air Motion Characteristics of Group A Outlets
(Straub *et al.* 1956)

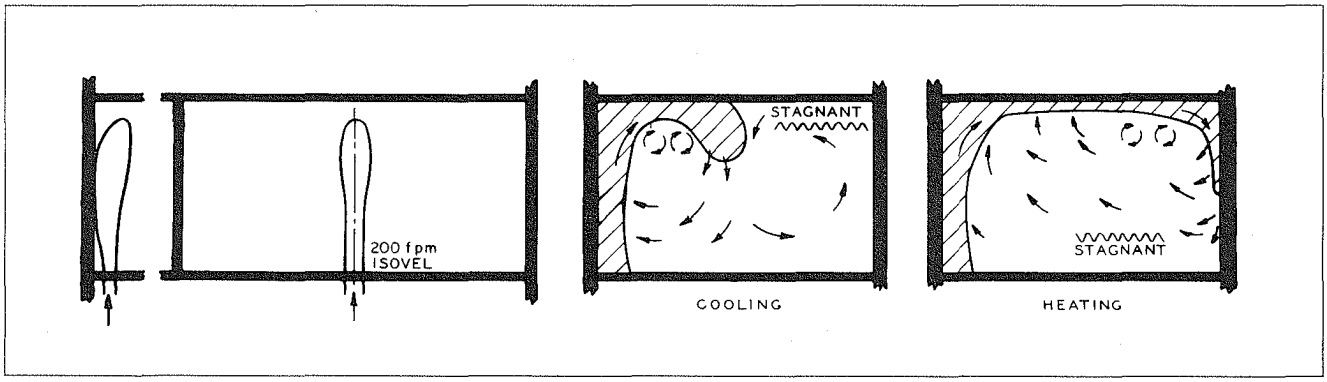

Fig. 2 Air Motion Characteristics of Group B Outlets
(Straub *et al.* 1956)

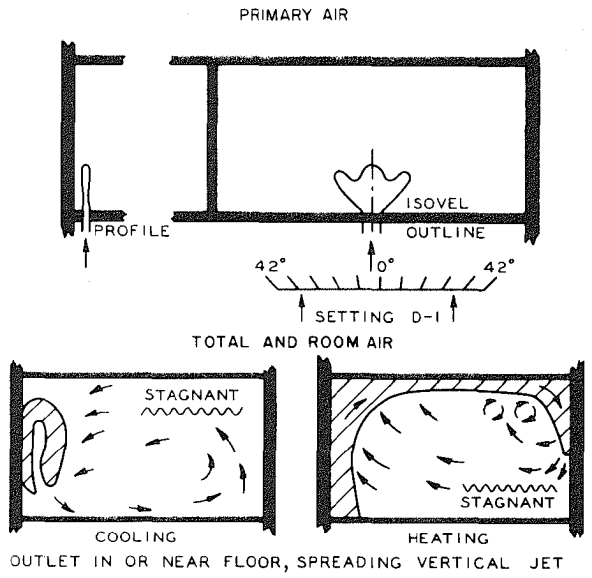

Fig. 3 Air Motion Characteristics of Group C Outlets
(Straub *et al.* 1956)

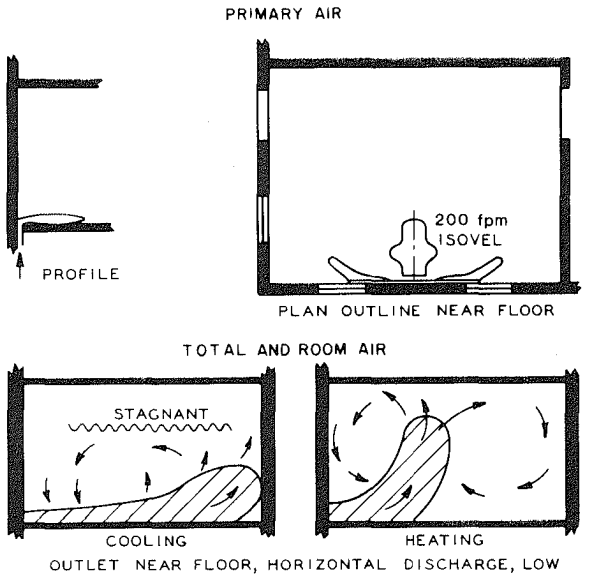

Fig. 4 Air Motion Characteristics of Group D Outlets
(Straub *et al.* 1956)

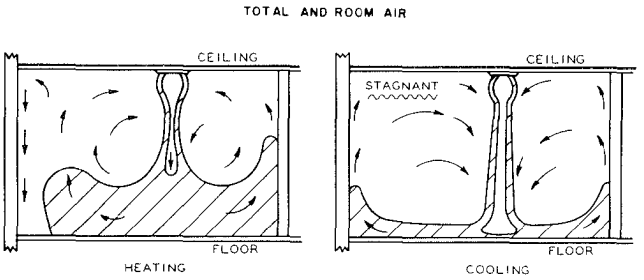

Fig. 5 Air Motion Characteristics of Group E Outlets
(Straub *et al.* 1956)

Since this zone results from natural convection currents, the air velocities within it are usually low (approximately 20 fpm), and the air stratifies in layers of increasing temperatures. The concept of a stagnant zone is important in properly applying and selecting outlets, since it considers the natural convection currents from warm and cold surfaces and internal loads.

4. A return inlet affects the room air motion only within its immediate vicinity. The intake should be located in the stagnant zone to return the warmest room air during cooling or the coolest room air during heating. The importance of the location depends on the relative size of the stagnant zone that results from various types of outlets.
5. The general room air motion (shown by clear areas in Figures 1 through 5) is a gentle drift toward the total air. Room conditions are maintained by the entrainment of the room air into the total airstream. The room air motion between the stagnant zone and the total air is relatively slow and uniform. The highest air motion occurs in and near the total airstreams.

Group A outlets. This group includes high sidewall grilles, sidewall diffusers, ceiling diffusers, linear ceiling diffusers, and similar outlets. High sidewall grilles and ceiling diffusers are illustrated in Figure 1.

The primary air envelopes (isovels) show a horizontal, two-jet pattern for the high sidewall and a 360° diffusion pattern for the ceiling outlet. Although variation of vane settings might cause a discharge in one, two, or three jets in the case of the sidewall outlet, or have a smaller diffusion angle for the ceiling outlet, the general effect in each is the same.

During cooling, the total air drops into the occupied zone at some distance from the outlet, which depends on air quantity, supply velocity, temperature differential between supply and room air, deflection setting, ceiling effect, and type of loading within the space. Analytical methods of relating some of these factors are presented in the section Room Air Distribution Theory.

The cooling diagram for the high sidewall outlet shows an overthrow condition, causing the total air to drop along the opposite wall and flow slowly for some distance across the floor. This condition should be avoided, since the total air region becomes one of high velocity accompanied by temperature depressions. Velocities of about 100 to 150 fpm may be found near the wall but will dissipate within about 4 in. of the wall.

The cooling diagram of the ceiling outlet shows that the total air movement is counteracted by the rising natural convection currents on the heated wall and, therefore, drops before reaching the wall. On the other hand, the total air reaches the inside wall and descends for some distance along it. With this type of outlet, temperature variations within the room are minimized, with minimal stagnant volume. Since the maximum velocity and the maximum temperature variation occur within and near the total air envelope, the drop region becomes important because it is an area with high effective draft temperature θ. Consequently, it is necessary to know how far the air drops before velocities and temperatures reach acceptable limits.

Since these outlets discharge horizontally near the ceiling, the warmest air in the room is mixed immediately with the cool primary air far above the occupied zone. Therefore, the outlets are capable of handling relatively large quantities of air at large temperature differentials.

During heating, warm supply air introduced at the ceiling can cause stratification in the space if there is insufficient induction of room air at the outlet. Selecting diffusers properly, limiting the room supply temperature differential, and maintaining air supply rates at a level high enough to ensure air mixing by induction provide adequate air diffusion and minimize stratification.

Several building codes and ASHRAE *Standard* 90.1 require sufficient insulation in exterior walls, so most perimeter spaces

can be heated effectively by ceiling air diffusion systems. Interior spaces, which generally have only cooling demand conditions, seldom require long-term heating and are seldom a design problem.

Flow rate and velocity for both heating and cooling are the same for outlet types in Figure 1. The heating diagram for the sidewall unit shows that, under these conditions, the total air does not descend along the wall. Consequently, higher velocities might be beneficial in eliminating the stagnant zone, since high velocity causes some warm air to reach floor level and counteract stratification of the stagnant region.

The heating diagram for the ceiling outlet shows the effect of the natural convection currents that produce a larger throw toward the cold exposed wall. The velocity of the total air toward the exposed wall complements the natural convection currents. However, the warm total air loses its downward momentum at its terminal point, and buoyancy forces cause it to rise toward the primary air. Although these forces are complementary, the heating effect of the total air replaces the cool natural convection currents with warm total air.

Group B outlets. This group includes floor registers, baseboard units, low sidewall units, linear-type grilles in the floor or windowsill, and similar outlets. Figure 2 illustrates a floor outlet adjacent to an inside wall.

Since these outlets have no deflecting vanes, the primary air is discharged in a single vertical jet. When the total air strikes the ceiling, it fans out in all directions from the point of contact and, during cooling, follows the ceiling for some distance before dropping toward the occupied zone. During heating, the total airflow follows the ceiling across the room, then descends partway down the exterior wall.

The cooling diagram shows that a stagnant zone forms outside the total air region above its terminal point. Below the stagnant zone, air temperature is uniform, effecting complete cooling. Also, space below the terminal point of the total air is cooled satisfactorily. For example, if total airflow is projected upward for 8 ft, the region from this level down to the floor will be cooled satisfactorily. This, however, does not apply to an extremely large space. Judgment to determine the acceptable size of the space outside the total air is needed. A distance of 15 to 20 ft between the drop region and the exposed wall is a conservative design value.

A comparison of Figures 1 and 2 for heating shows that the stagnant region is smaller for Group B than Group A outlets because the air entrained in the immediate vicinity of the outlet is taken mainly from the stagnant region, which is the coolest air in the room. This results in greater temperature equalization and less buoyancy in the total air than would occur with Group A outlets.

While the temperature gradients for both outlet groups are about the same, the stagnant layer for Group B is lower than that for Group A.

Group C outlets. This group includes floor diffusers, sidewall diffusers, linear-type diffusers, and other outlets installed in the floor or windowsill (Figure 3).

Although outlets of this group are related to Group B, they are characterized by wide-spreading jets and diffusing action. Total air and room air characteristics are similar to those of Group B, although the stagnant zone formed is larger during cooling and smaller during heating. Diffusion of the primary air usually causes the total air to fold back on the primary and total air during cooling, instead of following the ceiling. This diffusing action of the outlets makes it more difficult to project the cool air, but it also provides a greater area for induction of room air. This action is beneficial during heating, since the induced air comes from the lower regions of the room.

Group D outlets. This group includes baseboard and low sidewall registers and similar outlets (Figure 4), which discharge the primary air in single or multiple jets. However, since the air is discharged horizontally across the floor, the total air, during cooling, remains near the floor, and a large stagnant zone forms in the entire upper region of the room.

During heating, the total air rises toward the ceiling because of the buoyant effect of warm air. The temperature variations are uniform, except in the total air region.

Group E outlets. This group includes ceiling diffusers, linear-type grilles, sidewall diffusers and grilles, and similar outlets, mounted or designed for vertical downward air projection. Figure 5 shows the heating and cooling diagrams for this ceiling diffuser.

During cooling, the total air projects to and follows the floor, producing a stagnant region near the ceiling. During heating, the total airflow reaches the floor and folds back toward the ceiling. If projected air does not reach the floor, a stagnant zone results.

General Factors Affecting Outlet Performance

Effect of vanes. Vanes affect grille performance if their depth is at least equal to the distance between the vanes. If the vane ratio is less than unity, effective control of the airstream discharged from the grille by means of the vanes is impossible. Increasing the vane ratio above two has little or no effect, so vane ratios should be between one and two.

A grille discharging air uniformly forward (vanes in straight position) has a spread of 14 to 24°, depending on the type of outlet, duct approach, and discharge velocity. Turning the vanes influences the direction and throw of the discharged airstream.

A grille with diverging vanes (vertical vanes with uniformly increasing angular deflection from the centerline to a maximum at each end of 45°) has a spread of about 60° and reduces the throw considerably. With increasing divergence, the quantity of air discharged by a grille for a given upstream total pressure decreases.

A grille with converging vanes (vertical vanes with uniformly decreasing angular deflection from the centerline) has a slightly higher throw than a grille with straight vanes, but the spread is approximately the same for both settings. The airstream converges slightly for a short distance in front of the outlet and then spreads more rapidly than air discharged from a grille with straight vanes.

In addition to vertical vanes that normally spread the air horizontally, horizontal vanes may spread the air vertically. However, spreading the air vertically risks hitting beams or other obstructions or blowing primary air into the occupied zone at excessive velocities. On the other hand, vertical deflection may increase adherence to the ceiling and reduce the drop.

Effect of beamed ceilings and obstructions. In spaces with exposed beams, the outlets should be located below the bottom of the lowest beam level, preferably low enough to employ an upward or arched air path. The air path should be arched sufficiently to miss the beams and prevent the primary or induced airstream from striking furniture and obstacles and producing objectionable drafts (Wilson 1970). Obstructions influence airflow patterns and can reduce air distribution efficiency. Obstructions can reduce jet throw, increase air velocities in portions of the occupied zone, and create stagnant zones.

Variable air volume systems (VAV). The design of air distribution systems is usually based on the full load (heating/cooling). When only a partial load exists, VAV systems reduce the supply airflow, which, in turn, reduces the air velocity at the outlet. This decrease in outlet air velocity reduces the throw, which may cause a cold draft in the occupied zone or a poorly ventilated (stagnant) zone. Therefore, different operation modes of the system (airflow and initial temperature difference) should be considered in designing a VAV system air distribution (Zhivov 1990).

Displacement Ventilation

Conditioned air with a temperature slightly lower than the desired room air temperature in the occupied zone is supplied from air outlets at low air velocities (100 fpm or less). The outlets are

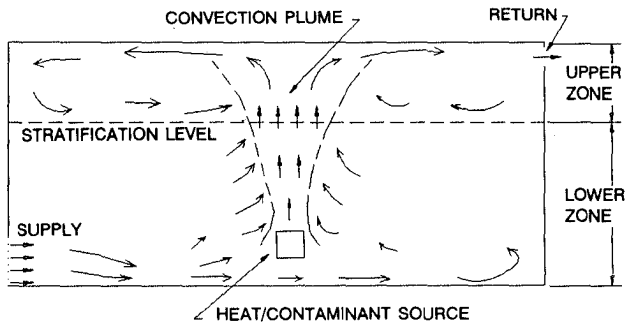

Fig. 6 Schematic of Displacement Ventilation

located at or near the floor level, and the supply air is directly introduced to the occupied zone. Returns are located at or close to the ceiling through which the warm room air is exhausted from the room. The supply air is spread over the floor and then rises as it is heated by the heat sources in the occupied zone. Heat sources (*e.g.*, person, computer) in the occupied zone create upward convective flows in the form of thermal plumes; these remove heat and contaminants which are less dense than the air from the occupied zone (Figure 6).

The air volume in the plumes increases as they rise because the plumes entrain ambient air. A stratification level exists where the airflow rate in the plumes equals the supply airflow rate. Two distinct zones are thus formed within the room, one lower zone below the stratification level and with no recirculation flow (close to displacement flow), and one upper zone, with recirculation flow (Figure 6). The height of the lower zone depends on the supply airflow rate and characteristics of heat sources and their distribution across the floor area. In a properly designed displacement ventilation system, the height of the lower zone is above the occupied zone so that the occupied zone can be ventilated effectively. For this type of system to function properly, a stable vertically stratified temperature field is essential.

In contrast to mixing ventilation, displacement ventilation is designed to minimize mixing of air within the occupied zone. The objective of the displacement ventilation is to create close to supply air conditions in the occupied zone. This type of ventilation was originally used in industrial buildings as an effective method for removing contaminants in the occupied zone. It is now also used for ventilating and cooling office buildings. However, local discomfort due to draft and vertical temperature gradient may be critical (Melikov and Nielsen 1989). Sandberg and Blomqvist (1989) suggest that the maximum convective cooling load in office buildings with displacement ventilation not exceed about 8 Btu/ft^2·h so that the maximum vertical temperature gradient in the occupied zone will not be larger than 5°F. This is equivalent to 1 cfm/ft^2 at a maximum cooling differential of 7.5°F. Kegel (1989) and Svensson (1989) suggest somewhat higher cooling load limits of 10 to 13 Btu/ft^2·h.

One way of increasing the cooling capacity of displacement ventilation systems is to recirculate some of the room air in the occupied zone through an induction circuit, *i.e.*, the room air is induced into the supply air and is mixed before discharge through the low-velocity air terminal device into the room. This reduces the room air temperature gradient for a given cooling load, thus allowing a higher limit of up to 16 Btu/ft^2·h (Jackman 1991).

Air diffusers with a large outlet area are used to supply air with low velocities. Displacement ventilation has been compared with conventional mixing-type ventilation (Svensson 1989, Seppanen *et al.* 1989, Stymne 1991). Design guidelines for displacement ventilation can be found in Scaret (1985), Jackman (1990, 1991), and Shilkrot and Zhivov (1992).

Unidirectional Airflow Ventilation

Air is either (1) supplied from the ceiling and exhausted through the floor or vice versa, or (2) supplied through the wall and exhausted through returns at the opposite wall. The outlets are uniformly distributed over the ceiling, floor, or wall to provide a low turbulent "plug"-type flow across the entire room. This type of system is mainly used for ventilating clean rooms, in which the main objective is to remove contaminant particles within the room. Details about clean room ventilation are described by ASHRAE (1991). Unidirectional flow ventilation is also used in certain areas, such as computer rooms, paint booths, etc.

Localized Ventilation

Air is supplied locally for occupied regions, such as desks in offices, seats in theaters and cinemas, or working places in industrial buildings. Conditioned air is supplied towards the breathing zone of the occupants to create comfortable conditions and/or to reduce the concentration of pollutants. Several special air diffusers are available. Figure 7 shows one arrangement, with diffusers placed on the desks in front of the occupants. In theaters and cinemas, air can be supplied through the grille or perforated panels in the back (Figure 8A), through the legs (Figures 8B and D) of the theater chairs, or through air diffusers installed in the floor under the chairs (Figure 8C). A scheme of air distribution through the back of the chair is presented on Figure 8E (Scheunemann 1989, Rowlinson and Croom 1987).

METHODS OF EVALUATION

Standards for Satisfactory Conditions

The object of air diffusion in warm air heating, ventilating, and air-conditioning systems is to create the proper combination of temperature, humidity, and air motion in the occupied zone of the conditioned room—from the floor to 6 ft above floor level (Miller 1989). To obtain comfort conditions within this zone, standard limits have been established as acceptable effective draft temperature, which combines the effects of air temperature, air motion, and relative humidity in terms of their physiological effects on a human body. Variation from accepted standards causes occupant discomfort. Lack of uniform conditions within the space or excessive fluctuation of conditions in the same part of the space also produce discomfort. Such discomfort can arise because of (1)

Fig. 8 Local Air Supply in Theaters

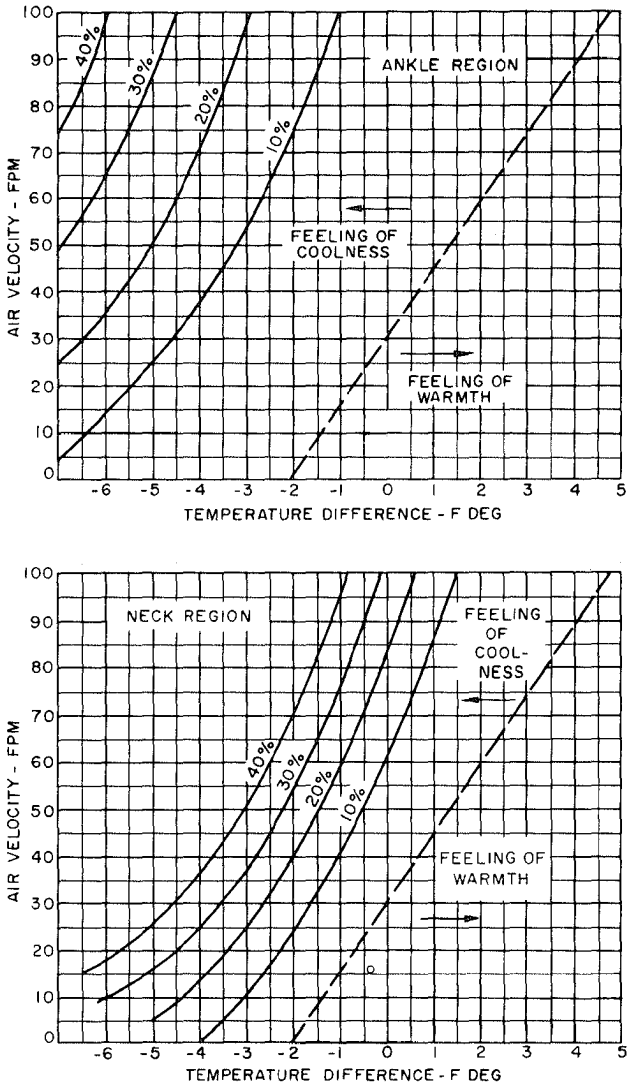

Fig. 9 Percentage of Occupants Objecting to Drafts in Air-Conditioned Rooms

excessive room air temperature variations (horizontally, vertically, or both), (2) excessive air motion (draft), (3) failure to deliver or distribute air according to the load requirements at different locations,(4) or overly rapid fluctuation of room temperature.

Koestel and Tuve (1955) and Reinmann *et al.* (1959) studied the effect of air motion on comfort and defined draft as any localized feeling of coolness or warmth of any portion of the body, due to both air movement and air temperature, with humidity and radiation considered constant. The warmth or coolness of a draft was measured above or below a controlled room condition of 76°F dry-bulb at the center of the room, 30 in. above the floor, with air moving at about 30 fpm.

To define the difference in effective draft temperature θ between any point in the occupied zone and the control condition, the investigators used the following equation proposed by Rydberg and Norback (1949) and modified by Straub in discussion of a paper by Koestel and Tuve (1955):

$$\theta = t_x - t_c - 0.07\,(V_x - 30) \qquad (1)$$

where

t_o = local airstream dry-bulb temperature, °F
t_c = average room dry-bulb temperature, °F
V_x = local airstream velocity, fpm

Equation (1) accounts for the feeling of coolness produced by air motion and is used to establish the neutral line in Figure 9. In summer, the local airstream temperature t_x is below the control temperature. Hence, both temperature and velocity terms are negative when velocity V_x is greater than 30 fpm and they both add to the feeling of coolness. If, in winter, t_x is above the control temperature, any air velocity above 30 fpm subtracts from the feeling of warmth produced by t_x. Therefore, it is usually possible to have zero difference in effective temperature between location, x, and the control point in winter, but not in summer.

Houghten *et al.* (1938) presented data that make it possible to statistically interpret the percentage of room occupants that will object to a given draft condition. Figure 6 presents the data in the form used by Koestel and Tuve (1955). The data show that a person tolerates higher velocities and lower temperatures at ankle

level than at neck level. Because of this, conditions in the zone extending from approximately 30 to 60 in. above the floor are more critical than conditions nearer the floor.

Room air velocities less than 50 fpm are generally preferred; however, Figure 6 shows that even higher velocities may be acceptable to some occupants. ASHRAE *Standard* 55-1992 recommends elevated air speeds at elevated air temperatures. No minimum air speeds are recommended for comfort, although air speeds below 20 fpm are usually imperceptible.

Figure 6 also shows that up to 20% of occupants will not accept an ankle-to-sitting-level gradient of about 4 °F. Poorly designed or operated systems in a heating mode can create this condition, which emphasizes the importance of proper selection and operation of perimeter systems. The section Typical Outlets and Their Performance describes possible regions of high room air velocities caused by various outlets; the section Outlet Location and Selection describes how to evaluate acceptable air diffusion.

Air Diffusion Performance Index (ADPI)

Comfort criteria. A high percentage of people are comfortable in sedentary (office) occupations where the effective draft temperature θ, as defined in Equation (1), is between −3 and 2 °F and the air velocity is less than 70 fpm. If several measurements of air velocity and air temperature were made throughout the occupied zone of an office, the ADPI would be defined as the percentage of locations where measurements that meet the previous specifications on effective draft temperature and air velocity were taken. If the ADPI is maximum (approaching 100%), the most desirable conditions are achieved (Miller and Nevins 1969, 1970, 1972, 1974; Miller 1971; Miller and Nash 1971; Nevins and Ward 1968; Nevins and Miller 1972).

The ADPI is based only on air velocity and effective draft temperature, a combination of local temperature differences from the room average, and is not directly related to the level of dry-bulb temperature or relative humidity. These and similar effects, such as mean radiant temperature, must be accounted for separately according to ASHRAE recommendations.

The ADPI is a measure of cooling mode conditions. Heating conditions can be evaluated using ASHRAE *Standard* 55-1992 guidelines or the ISO *Standard* 7730-84.

The following cooling zone design criteria for various air diffusion devices maximize the ADPI and comfort. These criteria also account for airflow rate, outlet size, manufacturer's design qualities, and dimensions of the room for which the system is designed.

Jet Throw

The throw of a jet is the distance from the diffuser to a point where the maximum velocity in the stream cross section has been reduced to a selected terminal velocity. For all diffusers, the terminal velocity V_T was selected as 50 fpm, except in the case of ceiling slot diffusers, where the terminal velocity was selected as 100 fpm. Each manufacturer gives data for the throw of a jet from various diffusers for isothermal conditions and without a boundary wall interfering with the jet. Throw data certified under ASHRAE *Standard* 70-72 must be taken under isothermal conditions; throw data not certified by this standard may be isothermal or not, as the manufacturer chooses.

The throw distance of a jet is denoted by T_V, where subscript V indicates the terminal velocity for which the throw is given. The characteristic room length is the distance from the diffuser to the nearest boundary wall in the principle horizontal direction of the airflow. However, where air injected into the room does not impinge on a wall surface but mixes with air from a neighboring diffuser, the characteristic length L is one-half the distance between diffusers, plus the distance the mixed jet travels downward to reach the occupied zone. Table 1 summarizes definitions of characteristic length for various diffusers.

Table 1 Characteristic Room Length for Several Diffusers

Diffuser Type	Characteristic Length L
High sidewall grille	Distance to wall perpendicular to jet
Circular ceiling diffuser	Distance to closest wall or intersecting air jet
Sill grille	Length of room in direction of jet flow
Ceiling slot diffuser	Distance to wall or midplane between outlets
Light troffer diffusers	Distance to midplane between outlets, plus distance from ceiling to top of occupied zone
Perforated, louvered ceiling diffusers	Distance to wall or midplane between outlets

The midplane between diffusers also can be considered the module line when diffusers serve equal modules throughout a space, and a characteristic length consideration can be based on module dimensions d.

Load Considerations

These recommendations cover cooling loads of up to 80 Btu/h·ft² of floor surface. The loading is distributed uniformly over the floor up to about 7 Btu/h·ft², lighting contributes about 10 Btu/h·ft², and the remainder is supplied by a concentrated load against one wall that simulates a business machine or a large sun-loaded window. Over this range of data, the maximum ADPI condition is lower for the highest loads; however, the optimum design condition changes only slightly with the load.

Design Conditions

The quantity of air must be known from other design specifications. If it is not known, the solution must be obtained by trial and error.

The devices for which data were obtained are (1) high sidewall grilles, (2) sill grilles, (3) two- and four-slot ceiling diffusers, (4) cone-type circular ceiling diffusers, (5) light troffer diffusers, and (6) square-faced perforated and louvered ceiling diffusers. Table 2 summarizes the results of the recommendations on values of

Table 2 Air Diffusion Performance Index (ADPI) Selection Guide

Terminal Device	Room Load, Btu/(h·ft²)	T_{50}/L for Max. ADPI	Maximum ADPI	For ADPI Greater Than	Range of $T_{0.25}/L$

PRINCIPLES OF ROOM AIR DISTRIBUTION

Air Jets

As a rule, air supplied into rooms through the various types of outlets (*e.g.*, grille-like, ceiling diffusers, perforated panels) is distributed by turbulent air jets. These air jets are the primary factor affecting room air motion; for further information on the relationship between the air jet and the occupied zone, see Baturin (1972), Christianson (1989), and Murakami (1992). If the air jet is not obstructed by walls, ceiling, or other obstructions, it is considered a *free jet*. If the air jet is attached to a surface, it is an *attached air jet*.

Characteristics of the air jet in a room might be influenced by reverse flows, created by the same jet entraining the ambient air. This air jet is called a *confined jet*. If the temperature of the supplied air is equal to the temperature of the ambient room air, the air jet is called an *isothermal jet*. A jet with an initial temperature different from the temperature of the ambient air is called a *nonisothermal jet*. The air temperature differential between supplied and ambient room air generates thermal forces in jets, affecting (1) the trajectory of the jet, (2) the location at which the jet attaches and separates from the ceiling/floor, and (3) the throw of the jet. The significance of such effects depends on the ratio between the thermal buoyancy and inertial forces (characterized by the Archimedes number Ar).

Depending on the diffuser type, air jets can be classified as follows:

- *Compact* air jets are formed by cylindrical tubes, nozzles, square or rectangular openings with small aspect ratio, unshaded or shaded by perforated plates, grilles etc. Compact air jets are three-dimensional and axisymmetric at least on some distance from the diffuser opening. The maximum velocity in the cross section of the compact jet is on the axis.
- *Linear* air jets are formed by slots or rectangular openings with a large aspect ratio. The jet flows are approximately two-dimensional. Air velocity is symmetric in the plane at which air velocities in the cross section are maximum. At some distance from the diffuser, linear air jets tend to transform into compact jets.
- *Radial* air jets are formed when the ceiling cylindrical air diffusers with flat discs or multidiffusers direct the air horizontally in all directions.
- *Conical* air jets are formed by cone-type or regulated multidiffuser ceiling-mounted air distribution devices. They have an axis of symmetry. The air flows parallel to the conical surface (the angle at the top of the cone is 120°) with the maximum velocities in the cross section perpendicular to the axis.
- *Incomplete radial* jets are formed by outlets with grilles having diverging vanes and a forced angle of expansion. At a distance, this jet tends to transform into a compact one.
- *Swirling* jets are forced by diffusers with vortex-forming devices. These devices create rotation, which has besides the axial component of velocity vectors, tangential and radial ones. Depending on the type of air diffuser, swirling jets can be compact, conical, or radial.

Isothermal Free Jet

The shape of jets at a short distance from the outlet face is very similar whether the outlet is round, rectangular, grille-like, or a perforated panel. The jet discharged from a round opening forms an expanding cone; jets from rectangular outlets rapidly pass from a rectangular to an elliptical cross-sectional shape and then to a circular shape, at a rate depending primarily on the aspect ratio and jet width. Even for wide-angle grilles and annular outlets, the similarities permit the same performance analysis for both.

For many conditions of jet discharge, it is possible to analyze jet performance and determine (1) the angle of divergence of the jet boundary, (2) the velocity patterns along the jet axis, (3) the velocity profile at any cross section in the zone of maximum engineering importance, and (4) the entrainment ratios in the same zone (Tuve 1953).

Using the data in this section, the following must be considered:

1. Since the method of finding the jet velocities is based on several approximations, the two recommended equations must be used cautiously for extreme axial and radial distances.
2. The characteristics of the low-velocity regions of ventilating jets are not well understood, and the effects at various Reynolds numbers are not fully known for axial or radial jets.
3. The quantitative treatment of the forces governing room air diffusion problems is limited, and nonisothermal conditions involving buoyant forces are more difficult to predict.
4. Most investigations have addressed free jets, whereas airstreams in practical room air diffusion are not free streams but are influenced by walls, ceilings, floors, and other obstructions.

Angle of Divergence

The angle of divergence is well-defined near the outlet face, but the boundary contours are billowy and easily affected by external influences. Here, as in the room, air movement has local eddies, vortices, and surges. The internal forces governing this air motion are extremely delicate (Nottage *et al.* 1952).

Measured angles of divergence (spread) for discharge into large open spaces usually range from 20 to 24° with an average of 22°. Coalescing jets for closely spaced multiple outlets expand at smaller angles, averaging 18°, and jets discharging into relatively small spaces show even smaller angles of expansion (McElroy 1943). In cases where the outlet area is small compared to the dimensions of the space normal to the jet, the jet may be considered free as long as

$$X \leq 1.5\sqrt{A_R} \tag{2}$$

where

X = distance from face of outlet, ft
A_R = cross-sectional area of confined space normal to jet, ft^2

Jet Expansion Zones

The full length of an air jet (compact, radial, linear, or conical), in terms of the maximum or centerline velocity and temperature differential at the cross section, can be divided into four zones:

Zone 1. A core zone; a short zone, extending about four diameters or widths from the outlet face, in which the maximum velocity (temperature) of the airstream remains practically unchanged.

Zone 2. A transition zone, the length of which depends on the type of diffuser, diffuser's aspect ratio, initial airflow turbulence, and so forth.

Zone 3. A zone of fully established turbulent flow, which may be 25 to 100 equivalent air diffuser diameters (widths for slot-type air diffusers).

Zone 4. A zone of diffuser jet degradation, where the maximum air velocity and temperature decreases rapidly. The distance to this zone and its length depends on the velocities and turbulence characteristics of the ambient air. In a few diameters, the air velocity becomes less than 50 fpm. Although this zone was studied by several researchers (Madison *et al.* 1946, Weinhold 1969), its characteristics are still not well understood.

Zone 3 is of major engineering importance because, in most cases, the diffuser jet enters the occupied area within this zone.

Centerline Velocities in Zones 1 and 2

In Zone 1, the ratio V_x/V_o is constant and equal to the ratio of the center velocity of the jet at the start of expansion to the average velocity. The ratio V_x/V_o varies from approximately 1.0 for rounded entrance nozzles to about 1.2 for straight pipe discharges; it has much higher values for diverging discharge outlets. Experimental evidence indicates that in Zone 2

$$V_x/V_o = \sqrt{K' H_o/X} \tag{3}$$

where

V_x = centerline velocity, fpm
V_o = $V_c/(C_d R_{fa})$ = average initial velocity at discharge from open-ended duct or across contracted stream at vena contracta of orifice or multiple-opening outlet, fpm
V_c = nominal velocity of discharge based on core area, fpm
C_d = coefficient of discharge (usually between 0.65 and 0.90)
R_{fa} = ratio of free area to gross (core) area
H_o = width of jet at outlet or at vena contracta, ft
K' = centerline velocity constant depending on outlet type and discharge pattern (see Table 3)
X = distance to centerline velocity V_x, ft

Aspect ratio (Tuve 1953) and turbulence (Nottage *et al.* 1952) primarily affect the centerline velocities in Zones 1 and 2. Aspect ratio has little effect on the terminal zone of the jet when H_o is greater than 4 in. This is particularly true of nonisothermal jets. When H_o is very small, it is possible for the induced air to penetrate the core of the jet and, thus, reduce the centerline velocities. The difference in performance between the radial-type outlet with a small H_o and the axial-type outlet with a large H_o shows the importance of the thickness of the jets.

When air is discharged from relatively large perforated panels, the constant velocity core formed by the coalescence of the individual jets extends a considerable distance from the panel face. In Zone 1, when the ratio (Distance from Panel)/$\sqrt{\text{Panel Area}}$ is less than 5, Equation (4)

$$V_x = 1.2\, V_o \sqrt{C_d R_{fa}} \tag{4}$$

should be used for estimating centerline velocities (Koestel *et al.* 1949).

Table 3 Recommended Values of Centerline Velocity Constant K or K' for Commercial Supply Outlets

Outlet Type	Discharge Pattern	Area A_o	K	K'
High sidewall grilles	0° deflection	Flow area	5.0	5.7
	Wide deflection	Flow area	3.7	4.2
High sidewall linear	Core less than 4 in. high	Flow area	3.9	4.4
	Core more than 4 in. high	Flow area	4.4	5.0
Low sidewall	Up and on wall, no spread	Free area	4.4	4.5
	Wide spread	Free area	2.6	3.0
Baseboard	Up and on wall, no spread	Free area	3.9	4.0
	Wide spread	Free area	1.8	2.0
Floor	No spread	Free area	4.1	4.7
	Wide spread	Free area	1.4	1.6
Ceiling circular directional	360° horizontal	Flow area	1.0	1.1
	4 way—little spread	Flow area	3.3	3.8
Ceiling linear	One way—horizontal along ceiling	Flow area	4.8	5.5

[a]These values are representative for the commercial type of outlet and discharge pattern given (Straub *et al.* 1956, 1957, Air Diffusion Council 1984).

Centerline Velocity in Zone 3

In Zone 3, maximum or centerline velocities of straight flow isothermal jets can be determined with accuracy from the equations

$$\frac{V_x}{V_o} = \frac{K D_o}{X} = \frac{K'\sqrt{A_o}}{X} \tag{5}$$

$$V_x = \frac{K' V_o \sqrt{A_o}}{X} = \frac{K' Q}{X\sqrt{A_o}} \tag{6}$$

$$V_x = \frac{K' Q}{X\sqrt{A_c C_d R_{fa}}} \tag{7}$$

where

K = proportionality constant, with $K' = 1.13\,K$
D_o = effective or equivalent diameter of stream at discharge from open-end duct or at contracted section, ft
A_o = $A_c C_d R_{fa}$ = effective area of stream at discharge from open-end duct or at contracted section, ft^2
A_c = measured gross (core) area of outlet, ft^2
Q = discharge from outlet, ft^3/min

Since A_o equals the effective area of the stream, the flow area for commercial registers and diffusers, according to ASHRAE *Standard* 70-72, can be used in Equation (5) with the appropriate value of K and K'.

Equation (5) is nondimensional and requires only that consistent units be used. Values of K and K' are listed in Table 4 (Tuve 1953, Koestel *et al.* 1950).

In multiple-opening outlets and annular ring outlets, the streams coalesce into a solid jet before actual jet expansion takes place. This coalescence affects the proportionality constants K or K' and accounts for some divergence in reported values for similar outlets.

For perforated panels of relatively large size, the values of K and K' given in Table 4 apply only when the ratio (Distance from Panel)/$\sqrt{\text{Panel Area}}$ is larger than 5 (see section Centerline Velocities in Zones 1 and 2).

Low-velocity test results, in the range $V_x < 150$ fpm, indicate that normal values of K and K' should be reduced about 20% for $V_x = 50$ fpm, as used later in Equation (10) for throw.

Table 4 Recommended Values of Centerline Velocity Constant for Standard Openings

	K		K'	
Type of Outlet	V_o = 500 to 1000 fpm	V_o = 2000 to 10,000 fpm	V_o = 500 to 1000 fpm	V_o = 2000 to 10,000 fpm
Free openings				
Round or square	5.0	6.2	5.7	7.0
Rectangular, large aspect ratio (<40)	4.3	5.3	4.9	6.0
Annular slots axial or radial[a]	—	—	3.9	4.8
Grilles and grids				
Free area 40% or more	4.1	5.0	4.7	5.7
Perforated panels				
Free area 3 to 5%	2.7	3.3	3.0	3.7
Free area 10 to 20%	3.5	4.3	4.0	4.9

[a]For radial slots, use X/H instead of $X/\sqrt{A}$. H is the height or width of the slot.
Note: K and K' are indexes of loss in axial kinetic energy. Interpolate as required. Departures from maximum value indicate losses in first and second zones when compared with the jet from a rounded-entrance, circular nozzle.

Determining Centerline Velocities

To correlate data from all four zones, centerline velocity ratios are plotted against distance from the outlet in Figure 9 according to Equation (3). A nomogram for calculating the parameters x/A_o and V_x/V_c from $X/\sqrt{A_c}$ and V_x/V_o through R_{fa} and C_d is given in the same illustration.

The variation of the centerline velocity ratio with distance from the outlet or, more properly, from start of jet expansion for Zones 1 and 2 is also shown in Figure 9. V_x/V_o is plotted against X/H_o and, for a range of aspect ratios, against $X/\sqrt{A}$ for the single value of $K' = 7.0$. Values of V_x/V_o for other values of K' can be obtained by direct proportioning of $\sqrt{K'}$ to $\sqrt{7.0}$.

The following example, which is solved in Figure 10, illustrates the use of Figure 9.

Example 1. A grille has a core area of 12 in. by 18.75 in., $R_{fa} = 0.90$, $C_d = 0.80$, and $K' = 5.0$. Find V_c (velocity through core area) when V_x is 50 fpm for a throw of 50 ft ($X = 50$).

Solution:

$$A_c = (12 \times 18.75)/144 = 1.56 \text{ ft}^2$$
$$X/\sqrt{A_c} = 50/1.25 = 40$$
$$A_o = 1.56 \times 0.80 \times 0.90 = 1.123 \text{ ft}^2$$
$$X/A_o = 50/1.06 = 47.2$$
$$V_x/V_o = K'\sqrt{A_o}/X = 5\sqrt{1.123}/50 = 0.106$$
$$V_x/V_c = V_x/V_o(C_d R_{fa}) = 0.106/(0.80 \times 0.90) = 0.147$$

For $V_x = 50$ fpm, $V_c = 50/0.147 = 340$ fpm
The quantity of air discharged is then

$$Q = V_c A_c = 340 \times 1.56 = 530 \text{ cfm}$$

Throw

Equation (8) can be transposed to determine the throw X of an outlet, if the discharge volume and the center velocity are known.

$$X = \frac{K'}{V_x}\frac{Q}{\sqrt{A_c C_d R_{fa}}} \tag{8}$$

Or, if $Z = \sqrt{C_d R_{fa}}$, then

$$X = \frac{K'}{V_x}\frac{Q}{Z\sqrt{A_c}} \tag{9}$$

The maximum throw L is usually defined as the distance from the outlet face where the centerline velocity is 50 fpm. Therefore, for $V_x = 50$ fpm

$$L = X = \frac{K'}{50}\frac{Q}{Z\sqrt{A_c}} \tag{10}$$

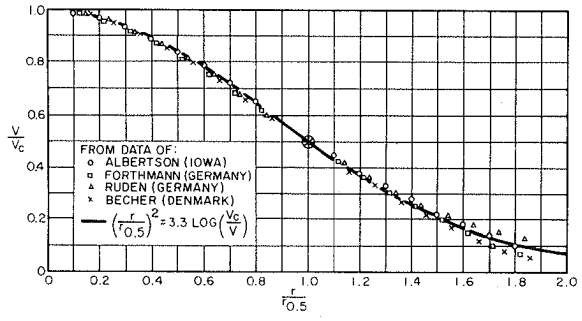

Fig. 11 Cross-Sectional Velocity Profiles for Straight-Flow Turbulent Jets

Any other terminal centerline velocity could be inserted in Equation (10) for V_x.

Velocity Profiles of Jets

In Zone 3 of both axial and radial jets, the velocity distribution may be expressed by a single curve (Figure 11) in terms of dimensionless coordinates; this same curve can be used as a good approximation for adjacent portions of Zones 2 and 4. Temperature and density differences have little effect on cross-sectional velocity profiles.

Velocity distribution in Zone 3 can be expressed by the Gauss error function or probability curve, which is approximated by Equation (11)

$$\left(\frac{r}{r_{0.5V}}\right)^2 = 3.3 \log \frac{V_x}{V} \tag{11}$$

where

r = radial distance of point under consideration from centerline of jet
$r_{0.5V}$ = radial distance in same cross-sectional plane from axis to point where velocity is one-half centerline velocity, *i.e.*, $V = 0.5\ V_x$
V_x = centerline velocity in same cross-sectional plane
V = actual velocity at point being considered

Experiments show that the conical angle for $r_{0.5V}$ is approximately one-half the total angle of divergence of a jet. The velocity profile curve for one-half a straight-flow turbulent jet (the other half being a symmetrical duplicate) is shown in Figure 11. For multiple-opening outlets, such as grilles or perforated panels, the velocity profiles are similar, but the angles of divergence are smaller.

Entrainment Ratios

Equations for the entrainment of circular jets and of jets from long slots follow.

For third-zone expansion of circular jets

$$\frac{Q_x}{Q_o} = \frac{2X}{K'\sqrt{A_o}} \tag{12}$$

By substituting from Equation (5)

$$\frac{Q_x}{Q_o} = 2\frac{V_o}{V_x} \tag{13}$$

For a long slot

$$\frac{Q_x}{Q_o} = \frac{\sqrt{2}}{K'}\sqrt{\frac{X}{H_o}} \tag{14}$$

or

$$\frac{Q_x}{Q_o} = \sqrt{2}\frac{V_o}{V_x} \tag{15}$$

where

Q_x = total volume flow rate at distance X from face of outlet, ft^3/min
Q_o = discharge from outlet, ft^3/min
X = distance from face of outlet, ft
K' = proportionality constant
A_o = effective area of stream at discharge from open-end duct or at contracted section, ft^2
H_o = width of slot, ft

Entrainment ratios are important to determine total air movement at a given distance from an outlet. With a given outlet, the entrainment ratio is proportional to the distance X [Equation (12)] or proportional to the square root of the distance X [Equation (14)] from the outlet. Equations (13) and (15) show that, for a fixed centerline velocity, the entrainment ratio is proportional to the outlet velocity. Equations (13) and (15) also show that, at the same centerline and outlet velocity, a circular jet has greater entrainment and total air movement than a long slot. Comparing Equations (12) and (14), the long slot should have a greater rate of induction. The entrainment ratio at a given distance is less with a large K' than with a small K'.

Isothermal Radial Flow Jets

In a radial jet, as with an axial jet, the cross-sectional area at any distance from the outlet varies as the square of this distance. Centerline velocity gradients and cross-sectional velocity profiles are similar to those of Zone 3 of axial jets, and the angles of divergence are about the same.

Jets from ceiling plaques have the same form as one-half a free radial jet. The jet is wider and longer than a free jet, with the maximum velocity close to the surface. Koestel (1957) provides an equation for radial flow outlets.

Nonisothermal Free Jet

When the temperature of introduced air is different from the room air temperature, the behavior of the diffuser air jet is affected by the thermal buoyancy due to air density difference. The trajectory of a nonisothermal jet introduced horizontally is determined by the Archimedes number (Baturin 1972):

$$\mathrm{Ar} = \frac{gL_o(t_o - t_s)}{V_o^2 T_s} \tag{16}$$

where

g = gravitational acceleration rate, ft/min^2
L_o = length scale of diffuser outlet equal to hydraulic diameter of outlet, ft
t_o = initial temperature of jet, °F
t_s = temperature of surrounding air, °F
V_s = initial air velocity of jet, fpm
T_s = room air temperature, K

The paths assumed by horizontally projected heated and chilled jets influenced by buoyant forces are significant in heating and cooling with wall outlets. Koestel's equation (1955) describes the behavior of these jets.

Helander *et al.* (1948, 1953, 1954, 1957), Yen *et al.* (1956), and Knaak (1957) developed equations for outlet characteristics that affect the downthrow of heated air. Koestel (1954, 1955) developed equations for temperatures and velocities in heated and chilled jets.

Surface Jets (Wall and Ceiling)

Jets discharging parallel to a surface with one edge of the outlet coinciding with the surface take the form of one-half of an axial jet discharging from an outlet twice as large, similar to radial jets from ceiling plaques. Entrainment takes place almost only along the surface of a half cone, and the maximum velocity remains close to the surface (Tuve 1953).

Values of K and K' are approximately those for a free jet multiplied by $\sqrt{2}$; *i.e.*, the normal maximum of 7.0 for K' for free jets becomes 9.9 for a similar jet adjacent to and discharged parallel to a surface, and $X/\sqrt{2A_o}$ should replace $X\sqrt{A_o}$ in Figure 9.

When a jet is discharged parallel to but at some distance from a solid surface (wall, ceiling, or floor), its expansion in the direction of the surface is reduced, and entrained air must be obtained by recirculation from the jet instead of from ambient air (McElroy 1943, Nottage *et al.* 1952, Zhang *et al.* 1990). The restriction of the solid surface to the jet entrainment induces the Coanda effect, which makes the jet attach to a surface after it leaves the diffuser outlet for a short distance. The jet then remains attached to the surface for some distance before separating from the surface again.

In nonisothermal cases, the trajectory of the jet is determined by the balance between the thermal buoyancy and the Coanda effect which depends on the jet momentum and the distance between the jet exit and the solid surface. The behavior of such nonisothermal surface jets have been studied by Kirkpatrick *et al.* (1991), Wilson *et al.* (1970), Oakes (1987), and Zhang *et al.* (1990), each addressing different factors. A more systematic study of these types of jets in room ventilation flows is needed to provide reliable guidelines for designing air diffusion systems.

Multiple Jets

Twin parallel air jets act independently until they interfere. The point of interference and its distance from the outlets varies with the distance between the outlets. From the outlets to the point of interference, the maximum velocity, as for a single jet, is on the centerline of each jet. Then, the velocity on a line midway between and parallel to the two jet centerlines increases until it equals the jet centerline velocity. From this point, a maximum velocity of the combined jet stream is on the midway line, and the profile seems to emanate from a single outlet of twice the area of one of the two outlets.

Koestel and Austin (1956) determined the spacing between outlets for noninterference between the jets. For a K value of 6.5, the outlets should be placed three to eight diameters apart, with V_o values from 500 to 1500 fpm.

Airflow in Occupied Zone in Mixing-Type Systems

Laboratory experiments on jets usually involve recirculated air with negligible resistance to flow on the return path of the jet air. Experiments in mine tunnels of small cross-sectional areas, where considerable resistance meets the return flow of jet air to outlets, show that expansion of the jet terminates abruptly at a distance independent of velocity of discharge and is only slightly affected by the size of the outlet. These distances are determined primarily by size and length of the return path. In a long 5 ft by 6 ft tunnel, a jet may not travel more than 25 ft; with a relatively large section (25 ft by 60 ft), it may travel more than 250 ft. McElroy (1943) provides data on this phase of jet expansion.

Zhang *et al.* (1990) found that air velocity in the occupied zone increased with the diffuser air velocity for the same ventilation rate. Therefore, the supply air velocity should be designed high enough to maintain the jet traveling in the desired direction to ensure good mixing before it reaches the occupied zone. Excessively high outlet air velocity would induce high air velocity in the occupied zone and result in thermal discomfort.

Turbulence Production and Transport

The turbulence within a room is mainly produced at the diffuser jet region by interaction of the supply air with the room air and with the solid surfaces (walls or ceiling) in the vicinity. It is then transported to other parts of the room, including the occupied zone (Zhang *et al.* 1991). Meanwhile, the turbulence is also damped by viscous effect. Air in the occupied zone usually contains very small amounts of turbulent kinetic energy as compared to that in the jet region. Since turbulence may cause thermal discomfort (Fanger *et al.* 1989), air diffusion systems should be designed so that the primary mixing between the introduced air and the room air occurs away from occupied regions.

SYSTEM FACTORS

Noise

The noise generated by diffusers transmits to the occupied space directly and cannot be attenuated. Therefore, the diffusion system design should meet the criteria of sound level as specified in Chapter 42 of the 1991 ASHRAE *Handbook—Applications.*

Duct Arrangements

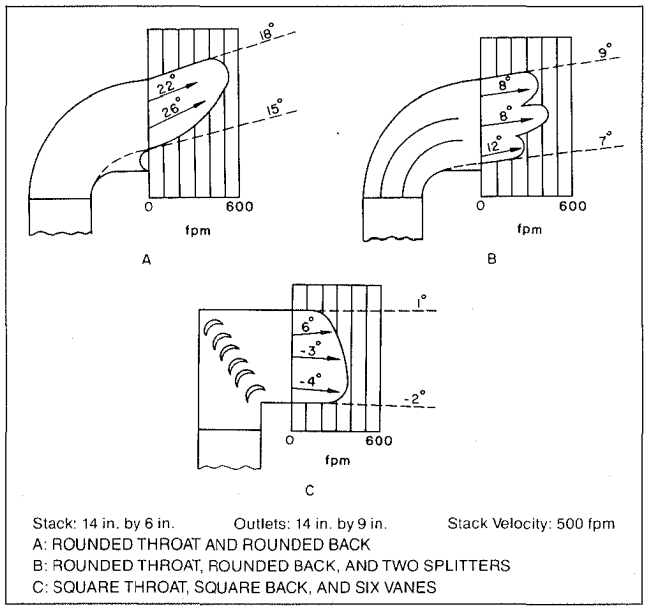
Duct approaches to diffuser outlets. The manner in which the airstream approaches the diffuser outlet is important. To obtain correct air diffusion, the velocity of the airstream must be as uniform as possible over the entire connection to the duct and must be perpendicular to the outlet face. Effects of improper duct approach generally cannot be corrected by the diffuser.

If the system is designed carefully, a wall grille installed at the end of a horizontal duct and a ceiling outlet at the end of a vertical duct receive the air perpendicularly and at uniform velocity over the entire duct cross section. However, few outlets are installed in this way. Most sidewall outlets are installed either at the end of vertical ducts or in the side of horizontal ducts, and most ceiling outlets are attached either directly to the bottom of horizontal ducts or to special vertical takeoff ducts that connect the outlet with the horizontal duct. In all these cases, special devices for directing and equalizing the airflow are necessary for proper direction and diffusion of the air.

The influence of the duct approach on outlet performance has been investigated for vertical stack heads with plain openings (Nelson *et al.* 1940) or equipped with grilles (Nelson *et al.* 1942) and side outlets on horizontal ducts (Nelson and Smedberg 1943). In tests conducted with the stack heads, splitters or guide vanes in the elbows at the top of the vertical stacks are needed, regardless of the shape of the elbows (whether rounded, square, or expanding types). Cushion chambers at the top of the stack heads are not beneficial. Figure 12 shows the direction of flow, diffusion, and velocity (measured 12 in. from the opening) of the air for various stack heads tested, expanding from a 14 in. by 6 in. stack to a 14 in. by 9 in. opening, without a grille. The air velocity for each was 500 fpm in the stack below the elbow, but the direction of flow and the diffusion pattern indicate performance obtained with nonexpanding elbows of similar shapes for velocities from 200 to 400 fpm.

In tests conducted with 3 in. by 10 in., 4 in. by 9 in., and 6 in. by 6 in. side outlets in a 6-in. by 20-in. horizontal duct at duct velocities of 200 to 1400 fpm in the horizontal duct section, multiple curved deflectors produced the best flow characteristics. Vertical guide strips in the outlet were not as effective as curved deflectors. A single scoop-type deflector at the outlet did not improve the flow pattern obtained from a plain outlet and, therefore, was not desirable.

Return and exhaust openings. The selection of return and exhaust openings depends on (1) velocity in the occupied zone near the openings, (2) permissible pressure drop through the openings, and (3) noise.



Stack: 14 in. by 6 in. Outlets: 14 in. by 9 in. Stack Velocity: 500 fpm
A: ROUNDED THROAT AND ROUNDED BACK
B: ROUNDED THROAT, ROUNDED BACK, AND TWO SPLITTERS
C: SQUARE THROAT, SQUARE BACK, AND SIX VANES

Fig. 12 Outlet Velocity and Air Direction Diagrams for Stack Heads with Expanding Outlets

Velocity. Airflow patterns as well as room air movement are not influenced by the location of the return and exhaust outlets at a distance more than one characteristic length of the return or exhaust opening (*e.g.*, square root of the opening area). Air handled by the opening approaches the opening from all directions, and its velocity decreases rapidly as the distance from the opening increases. Therefore, drafty conditions rarely occur near return openings. Table 4 shows recommended return opening face velocities.

Permissible pressure drop. Permissible pressure drop depends on the choice of the designer. Proper pressure drop allowances should be made for control or directive devices.

Noise. The problem of return opening noise is the same as that for supply outlets. In computing resultant room noise levels from the operation of an air-conditioning system, the return opening must be included as part of the total grille area.

Return and Exhaust Opening Location

The openings should be located to minimize short-circuiting of supply air. If air is supplied by the jets attached to the ceiling, exhaust openings should be located between the jets or at the other side of the room away from the supply air jets. In rooms with temperature stratification along its height, such as in foundries, computer rooms, theaters, bars, kitchens, dining rooms, and club rooms, exhaust openings should be located near the ceiling to collect warm air, odors, and fumes.

For industrial rooms with gas release, selection of exhaust opening locations depends on the specific weight of the released gases and their temperature; the locations should be specified for each application.

Exhaust outlets located in walls and doors, depending on their elevation, have the characteristics of either floor or ceiling returns. In large buildings with many small rooms, return air may be brought through door grilles or door undercuts into the corridors and then to a common return or exhaust. The pressure drop through door returns should not be excessive, or the air diffusion to the room may be seriously unbalanced by opening or closing the doors. Outward leakage through doors or windows cannot be counted on for dependable results.

System Balancing

In designing a system, ducts and diffusers should be sized so that the supply of air is distributed properly. However, for flexibility, use standard sizes and allow for future redistribution; the system, as designed, may not be self-balancing. Chapter 34 of the 1991 ASHRAE *Handbook—Applications* describes the procedures used to balance air distribution systems.

SYSTEM DESIGN

Design Procedure

1. Determine the air volume requirements and room size.
2. Select the tentative diffuser type and location within room.
3. Determine the room's characteristic length L (Table 1).
4. Select the recommended T_V/L ratio from Table 2.
5. Calculate the throw distance T_V by multiplying the recommended T_V/L ratio from Table 2 by the room length L.
6. Locate the appropriate outlet size from the manufacturer's catalog.
7. Ensure that this outlet meets other imposed specifications, such as noise and static pressure.

Example 2.

Specifications:	
Room size	20 ft by 12 ft with 9-ft ceiling
Type device	High sidewall grille, located at the center of 12-ft endwall, 9 in. from ceiling
Loading	Uniform, 10 Btu/h·ft^2 or 2400 Btu/h
Air volume	1 cfm/ft^2 or 240 cfm for the one outlet
Data required:	
Characteristic length	L = 20 ft (Length of room: Table 1)
Recommended	T_V/L = 1.5 (Table 2)
Throw to 50 fpm	T_{50} = 1.5 × 20 = 30 ft

Refer to the manufacturer's catalog for a size that gives this isothermal throw to 50 fpm. Manufacturer recommends the following sizes, when vanes are straight, discharging 240 cfm: 16 in. by 4 in., 12 in. by 5 in., or 10 in. by 6 in.

Outlet Location and Type Selection

No criteria have been established for choosing among the six types of outlets to obtain an optimum ADPI. All outlets tested, when used according to these recommendations, can have ADPI values that are satisfactory (greater than 90% for loads less than 40 Btu/h·ft^2).

The design of an air distribution and air diffusion system is influenced by the same factors as those influencing the design of an air-conditioning plant—building's use, size, and construction type. Location and selection of the supply outlets is further influenced by the interior design of the building, local sources of heat gain or loss, and outlet performance and design.

Local sources of heat gain or loss promote convection currents or cause stratification; they may, therefore, determine both the type and location of the supply outlets. Outlets should be located to neutralize any undesirable convection currents set up by a concentrated load. If a concentrated heat source is located at the occupancy level of the room, the heating effect can be counteracted (1) by directing cool air toward the heat source or (2) by locating an exhaust or return grille adjacent to the heat source. The second method is more economical for cooling applications, since heat is withdrawn at its source rather than dissipated into the conditioned space. Where lighting loads are heavy (5 W/ft^2) and ceilings relatively high (above 15 ft), outlets should be located below the lighting load, and the stratified warm air should be removed by an exhaust or return fan. An exhaust fan is recommended if the wet-bulb temperature of the air is above that of the outdoors; a return fan is recommended if the wet-bulb temperature is below this temperature. These methods reduce the requirements for supply air. Enclosed lights are more economical than exposed lights, since a considerable portion of the energy is radiant.

Based on the analysis of the outlet performance tests conducted by Straub *et al.* (1956, 1957), the following are selection considerations for outlet types in Groups A to E:

Group A outlets. Outlets mounted in or near the ceiling with horizontal air discharge should not be used with temperature differentials exceeding 25°F during heating. Consequently, such outlets should be used for heating buildings located in regions where winter heating is only a minor problem and, in northern latitudes, solely for interior spaces. However, these outlets are particularly suited for cooling and can be used with high airflow rates and large temperature differentials. They are usually selected for their cooling characteristics.

The performance of these outlets is affected by various factors. Vane deflection settings reduce throw and drop by changing air from a single straight jet to a wide-spreading or fanned out jet. Accordingly, a sidewall outlet with 0° deflection has a longer throw and a greater drop than a ceiling diffuser with a single 360° angle of deflection. Sidewall grilles and similar outlets with other deflection settings may have performance characteristics between these two extremes.

Wide deflection settings also cause a ceiling effect, which increases the throw and decreases the drop. To prevent smudging, the total air should be directed away from the ceiling, but this rarely is practicable, except for very high ceilings. For optimum air diffusion in areas without high ceilings, total air should scrub the ceiling surface.

Drop increases and throw decreases with larger temperature differentials. For constant temperature differential, airflow rate affects drop more than velocity. Therefore, to avoid drop, several small outlets instead of one large outlet may be better in a room .

With the data in the section Isothermal Jets, the throw may be selected for a portion of the distance between the outlet and wall or, preferably, for the entire distance. For outlets in opposite walls, the throw should be one-half the distance between the walls. Following the above recommendations, the air drops before striking the opposite wall or the opposing airstream. To counteract specific sources of heat gain or to provide higher air motion in rooms with high ceilings, it may be necessary to select a longer throw. In no case should the drop exceed the distance from the outlet to the 6-ft level.

To maintain maximum ventilation effectiveness with ceiling diffusers, throws should be kept as long as possible. With VAV designs, some overthrow at maximum design volumes will be desirable—the highest induction can be maintained at reduced flows. Adequate induction by a ceiling-mounted diffuser prevents short-circuiting of unmixed supply air between supply outlet and ceiling-mounted returns.

Group B outlets. In selecting these outlets, it is important to provide enough throw to project the air high enough for proper cooling in the occupied zone. An increase of supply air velocity improves air diffusion during both heating and cooling. Also, during heating and cooling, a terminal velocity of about 150 fpm is found at the same distance from the floor. Therefore, outlets should be selected from the data given in the Isothermal Jets section, with throw based on a terminal velocity of 150 fpm.

With outlets installed near the exposed wall, the primary air is drawn toward the wall, resulting in a wall effect similar to the ceiling effect for ceiling outlets. This scrubbing of the wall increases heat gain or loss. To reduce scrubbing, outlets should be installed some distance from the wall, or the supply air should be deflected at an angle away from the wall. However, the distance should not be too large, nor the angle too wide, to prevent the air from dropping into the occupied zone before it reaches maximum projection. A distance of 6 in. and an angle of 15° is satisfactory.

These outlets do not counteract natural convection currents, unless sufficient outlets are installed around the perimeter of the space—preferably in locations of greatest heat gain or loss (under windows). The effect of drapes and blinds must be considered with outlets installed near windows. If installed correctly, outlets of this type handle large airflow rates with uniform air motion and temperatures.

Group C outlets. These outlets can be used for heating, even with severe heat load conditions. Higher supply velocities produce better room air diffusion than lower velocities, but velocity is not critical in selecting these units for heating.

To achieve the required projection for cooling, the outlets should be used with temperature differentials of less than 15°F. With higher temperature differentials, supply air velocity is not sufficient to project the total air up to the desired level.

The outlets have been used successfully for residential heating, but they may also offer a solution for applications where heating requirements are severe and cooling requirements are moderate. For throw, refer to the Isothermal Jets section.

Group D outlets. This type of outlet directs high-velocity total air into the occupied zone, and, therefore, is not recommended for comfort, particularly for summer cooling. If used for heating, outlet velocities should not be higher than 300 fpm, so that air velocities in the occupied zone will not be excessive. These outlets have been applied successfully to process installations where controlled air velocities are desired.

Group E outlets. The heating and cooling diagrams for these outlets show different throws that become critical in selecting and applying these outlets. Since the total air enters the occupied zone for both cooling and heating, outlets are used for either cooling or heating—seldom for both.

During cooling, temperature differential, supply air velocity, and airflow rate have considerable influence on projection. Therefore, low values of each should be selected.

During heating, it is important to select the correct supply air velocity to project the warm air into the occupied zone. Temperature differential is also critical, because a small temperature differential reduces variation of the throw during the cyclic operation of the supply air temperature. Vane setting for deflection is as important here as it is for Group B and C outlets.

Investigations by Nevins and Ward (1968) and Miller and Nevins (1969) in full-scale interior test rooms indicate that air temperatures and velocities throughout a room cooled by a ventilating ceiling are a linear function of room load (heat load per unit area) and are not affected significantly by variations in ceiling type, total air temperature differential, or air volume flow rate. Higher room loading produces wider room air temperature variations and higher velocities, which decrease performance.

These studies also found no appreciable difference in the performance of air diffusing ceilings and circular ceiling diffusers for lower room loads (20 Btu/h·ft^2). For higher room loads (80 Btu/h·ft^2), an air-diffusing ceiling system has only slightly larger vertical temperature variations and slightly lower room air velocities than a ceiling diffuser system.

When the ventilating ceiling is used at exterior exposures, the additional load at the perimeter must be considered. During heating operation, the designer must provide for the cold wall effect, as with any ceiling supply diffusion system. The sound generated by the air supply device must also be considered in total system analysis to ensure that room sound levels do not exceed the design criteria.

Return Air Design for Optimum Performance

An HVAC system operating in the cooling mode performs best when generated heat is removed at its source rather than distributed throughout the conditioned space. Heat from solar and miscellaneous loads such as machinery and floor or desk-mounted lamps is difficult to remove at the source. However, return air flowing over ceiling-mounted lighting fixtures keeps most of that heat from being distributed into the conditioned space. Besides

Table 5 Recommended Return Inlet Face Velocities

Inlet Location	Velocity over Gross Area, fpm
Above occupied zone	800 up
Within occupied zone, not near seats	600 to 800
Within occupied zone, near seats	400 to 600
Door or wall louvers	200 to 300
Through undercut area of doors	200 to 300

increasing HVAC system efficiency, return air lighting fixtures improve light output and extend the lamp life. The manufacturers of fixtures, ceiling grids, and grilles give performance information (airflow rate, pressure drop, and heat removal rate) of their product. Ball *et al.* (1971) found that the heat removal performance of return air fixtures covers a narrow range.

With a suspended ceiling, low operating static pressure across the ceiling must be maintained. Failure to do so can result in return air being forced around the edges of the ceiling panels or, in some cases, through the ceiling panels. The result is often a soiled ceiling and a mechanical system that is choked for return air. To avoid this, the static pressure difference across the ceiling should be as low as possible. If necessary, slotted tees or grilles can be used with return air fixtures to obtain the specified pressure drop. A maximum pressure drop of 0.02 to 0.03 in. of water is acceptable under most conditions.

At the typical air supply rates found in office interior zone spaces (usually less than 1.5 cfm/ft^2) and with adequate induction at the supply diffusers, the location of the return diffuser has no effect on air patterns in the space. For most office spaces, it is only necessary that sufficient return outlets be provided to maintain inlet velocities within recommendations (see Table 5).

In spaces expected to operate in a cooling mode most of the time, returning the warmest air in the space can effectively reduce energy costs and increase circulation in the space. This is especially true in climates where economizer systems operate for long periods during the year. In very high ceiling spaces, with atria, skylights, or large vertical glass surfaces, and where the highest areas are unoccupied, air stratification may be used as an energy-saving measure, by locating returns near the occupied zone.

Recommendations for Ceiling-Mounted Air Diffuser Systems

For the best thermal comfort conditions and highest ventilation effectiveness in an occupied space (*i.e.*, office or retail store), the entire system performance of air diffusers should be considered. This is particularly true for open spaces, where airstreams from diffusers may interact with each other, and for perimeter spaces, where airstreams from diffusers interact with hot or cold perimeter walls. While throw data for an individual diffuser is used in system design, an air diffuser system should maintain a high quality of air diffusion in the occupied space. This is achieved with low temperature variation, good air mixing, and no objectionable drafts in the occupied space (typically 6 in. to 6 ft. above the floor).

Adequate ventilation requires that the selected diffusers effectively mix (by induction) the total air in the room with the supplied conditioned air, which is assumed to contain adequate ventilation air.

Interior spaces. An interior space is conditioned exclusively for cooling loads, except after unoccupied periods when the space may have cooled to below a comfortable temperature. Tests by Miller *et al.* (1970, 1971, 1979) and Hart and Int-Hout (1981) suggest that the air diffusion performance index (ADPI) can be improved by moving diffusers closer together (*i.e.*, specifying more diffusers for a given space and air quantity) and by limiting the value of the supply air/room air temperature difference. In a given system of diffusers, these studies found an optimum operating range of air volumes at a given thermal load. The operating load varies with diffuser design, ceiling height, thermal load, and diffuser orientation. This information can be obtained by constructing a mock-up representing the proposed building space, with several alternatives tested for ADPI values, in accordance with ASHRAE *Standard* 113-90. Usually, the diffuser manufacturer has performed these tests and can provide the best choice of design options for a particular building. For a VAV system, the diffuser spacing selection should not be based on maximum or design air volumes but rather on the air volume range where the system is expected to operate most of the time. For VAV applications, Miller (1979) recommends that the designer consider the expected variation range in the outlet air volume to ensure that ADPI values remain above a specified minimum.

Perimeter spaces. All-air mechanical systems that handle both heating and cooling thermal loads are commonly used in modern office buildings instead of using baseboards for heating and forced air for cooling. State energy codes (most based on ASHRAE *Standard* 90) require that commercial buildings have exterior walls that meet minimum thermal performance criteria for a particular location. Typically, walls of new buildings have design heat losses as low as 200 to 300 Btu/h per linear foot of wall.

A successful all-air heating-cooling mechanical system requires the designer to consider several design variables that have been the subject of research by Hart and Int-Hout (1980), Lorch and Straub (1983), and Rousseau (1983). The most important design variables include:

- Supply air/room air temperature difference
- Diffuser type and design
- Design heating and cooling loads
- Supply air volumes
- Distance between diffusers and perimeter wall
- Direction of air throw (toward wall, away from wall, or both)
- Ceiling height
- Desired air diffusion performance criteria

The diffuser manufacturer is best able to recommend the use of equipment.

For an office environment in cooling mode, the design goal should be an ADPI greater than 80. The ADPI should not be used as a measure of performance for heating conditions. In both cases, ASHRAE *Standard* 55-1992 recommends that the maximum temperature gradient should not exceed 5 °F (where temperature gradient refers to the difference between temperatures at any two points). Linear diffusers placed parallel to the perimeter wall perform well. For year-round operation, linear diffusers with two-way throw (*i.e.*, that throw air both toward and away from the perimeter wall) work best. Lorch and Straub (1983) reported optimum performance with a diffuser that throws warm air toward the perimeter wall under heating season conditions and chilled air in both directions under cooling season conditions. All researchers found less than optimum performance with high discharge temperatures (greater than 15 °F above ambient), both with one-way throw of air away from a cold wall and with one-way throw with chilled air toward the perimeter wall. Under heating season conditions, the supply air temperature must be limited to avoid excessive thermal stratification. To resolve any uncertainty about performance, a mock-up should be constructed with provisions for a cold wall; several variations of the design should be tested. As a result, the best diffuser wall spacing and supply air volumes can be selected. The ADPI or room temperature gradients or both, measured in accordance with ASHRAE *Standard* 113-90, can help gage system performance.

The following principles provide the best air diffusion quality and minimum energy use:

- For cooling load conditions, return air should exhaust from a location that takes advantage of any thermal stratification

design. In many cases, this should be a high point to take advantage of rising warm air. Cooling supply air should be introduced as close to the heat sources as possible. Alternately, stratification designs may condition only part of the total space. In these cases, conditioned air is supplied and exhausted as close to the occupants as possible. In either case, comfort zone temperature gradients should be maintained within 5 °F.

- For heating load conditions, thermal stratification should be discouraged. Heat should be introduced at points low in the large space. Ceiling-mounted fans may reduce stratification.

CHAPTER 32

DUCT DESIGN

Bernoulli Equation 32.1
Head and Pressure 32.2
System Analysis 32.2
Fluid Resistance 32.4
Frictional Losses 32.4
Dynamic Losses 32.6
Ductwork Sectional Losses 32.11
Fan-System Interface 32.11
Duct Design Considerations 32.13
Duct Design Methods 32.17
HVAC Duct Design Procedures 32.19
Industrial Exhaust System Duct Design 32.21
Fitting Loss Coefficients 32.28

COMMERCIAL or industrial air duct system design must consider (1) space availability, (2) space air diffusion, (3) noise levels, (4) duct leakage, (5) duct heat gains and losses, (6) balancing, (7) fire and smoke control, (8) initial investment cost, and (9) system operating cost.

Deficiencies in duct design can result in systems that operate incorrectly or are expensive to own and operate. Poor air distribution can cause discomfort; lack of sound attenuators may permit objectionable noise levels. Poorly designed sections of ductwork can result in unbalanced systems. Faulty duct construction or lack of duct sealing produces inadequate airflow rates at the terminals. Proper duct insulation eliminates the problem caused by excessive heat gain or loss.

In this chapter, system design considerations and the calculation of a system's frictional and dynamic resistance to airflow are considered. Chapter 16 of the 1992 ASHRAE *Handbook—Systems and Equipment* examines duct construction and presents construction standards for residential, commercial, and industrial heating, ventilating, air-conditioning, and exhaust systems.

BERNOULLI EQUATION

Bernoulli's equation can be developed by equating the forces on an element of a stream tube in a frictionless fluid flow to the rate of momentum change. On integrating this relationship for steady flow, the following expression (Osborne 1966) results:

$$\frac{v^2}{2g_c} + \int \frac{dP}{\rho} + \frac{gz}{g_c} = \text{constant, ft-lb}_f/\text{lb}_m \qquad (1)$$

where

v = streamline (local) velocity, ft/s
g_c = dimensional constant, 32.2 $(\text{lb}_m\text{-ft})/(\text{lb}_f\text{-s}^2)$
P = absolute pressure, lb_f/ft^2
ρ = density, lb_m/ft^3
g = acceleration due to gravity, ft/s^2
z = elevation, ft

Assuming constant fluid density within the system, Equation (1) reduces to:

$$\frac{v^2}{2g_c} + \frac{P}{\rho} + \frac{gz}{g_c} = \text{constant, ft-lb}_f/\text{lb}_m \qquad (2)$$

Although Equation (2) was derived for steady flow along a stream tube of an ideal frictionless flow, it can be extended to analyze flow through ducts in real systems. In terms of pressure, the relationship for fluid resistance between two sections is:

$$\frac{\rho_1 V_1^2}{2g_c} + P_1 + \gamma z_1 = \frac{\rho_2 V_2^2}{2g_c} + P_2 + \gamma z_2 + \Delta p, \frac{\text{ft-lb}_f}{\text{ft}^3} \qquad (3)$$

where

V = average duct velocity, ft/s
Δp = total pressure loss due to friction and dynamic losses between stations 1 and 2, lb_f/ft^2
γ = $\rho g/g_c$ specific weight, lb_f/ft^3

In Equation (3), V (section average velocity) replaces v (streamline velocity) because experimentally determined loss coefficients allow for errors in calculating $\rho v^2/2g_c$ (velocity pressure) across streamlines.

Add to, and subtract the quantities p_{z1} and p_{z2} from each side of Equation (3), respectively, where p_{z1} and p_{z2} are the values of atmospheric air at heights z_1 and z_2. Thus:

$$\frac{\rho_1 V_1^2}{2g_c} + P_1 + (p_{z1} - p_{z1}) + \gamma z_1 = \frac{\rho_2 V_2^2}{2g_c} + P_2 + (p_{z2} - p_{z2}) + \gamma z_2 + \Delta p \qquad (4)$$

The atmospheric pressure at any elevation (p_{z1} and p_{z2}) expressed in terms of the atmospheric pressure at the same datum elevation (p_a) is given by:

$$p_{z1} = p_a - (g/g_c)\,\rho_a\, z_1 \qquad (5)$$

$$p_{z2} = p_a - (g/g_c)\,\rho_a\, z_2 \qquad (6)$$

Substituting Equations (5) and (6) into Equation (4) and simplifying yields the total pressure change between stations 1 and 2. Air densities ρ_1 and ρ_2 are assumed equal at heights z_1 and z_2, thus $\rho_1 = \rho_2 = \rho$.

$$\Delta p_{1-2} = \left(p_{s,1} + \frac{\rho V_1^2}{2g_c}\right) - \left(p_{s,2} + \frac{\rho V_2^2}{2g_c}\right) = \Delta p - \frac{g}{g_c}(\rho_a - \rho)(z_2 - z_1) \qquad (7)$$

where

$p_{s,1}$ = static pressure, gage at elevation z_1 $(P - p_{z1})$, lb_f/ft^2
$p_{s,2}$ = static pressure, gage at elevation z_2 $(P - p_{z2})$, lb_f/ft^2
V_1 = average velocity at station 1, ft/s
V_2 = average velocity at station 2, ft/s
ρ_a = density of ambient air, lb_m/ft^3

The preparation of this chapter is assigned to TC 5.2, Duct Design.

ρ = density of air or gas within duct, lb_m/ft^3
Δp_{1-2} = total pressure change between stations 1 and 2, lb_f/ft^2
Δp = total pressure loss due to friction and dynamic losses between stations 1 and 2, lb_f/ft^2

HEAD AND PRESSURE

The terms *head* and *pressure* are often used interchangeably; however, head is the height of a fluid column supported by fluid flow, while pressure is the normal force per unit area. For liquids, it is convenient to measure the head in terms of the flowing fluid. With a gas or air, however, it is customary to measure pressure on a column of liquid.

Static Pressure

The term $(pg_c/\rho g)$ is static head; p is static pressure.

Velocity Pressure

The term $(V^2/2g)$ refers to velocity head, and the term $(\rho V^2/2g_c)$ to velocity pressure. Although velocity head is independent of fluid density, velocity pressure calculated by Equation (8) is not.

$$p_v = \rho\,(V/1097)^2 \tag{8}$$

where

p_v = velocity pressure, in. of water
V = fluid mean velocity, fpm

For air at standard conditions (0.075 lb_m/ft^3), Equation (8) becomes:

$$p_v = (V/4005)^2 \tag{9}$$

Velocity is calculated by Equation (10) or (11).

$$V = 144Q/A \tag{10}$$

where

Q = airflow rate, cfm
A = cross-sectional area of duct, in^2

$$V = Q/A \tag{11}$$

where

A = cross-sectional area of duct, ft^2

Total Pressure

Total pressure is the sum of static pressure and velocity pressure:

$$p_t = p_s + \rho\,(V/1097)^2 \tag{12}$$

or

$$p_t = p_s + p_v \tag{13}$$

where

p_t = total pressure, in. of water
p_s = static pressure, in. of water

Instruments

The range, precision, and limitations of instruments for measuring pressure and velocity are discussed in Chapter 13. The manometer is a simple and useful means for measuring partial vacuum and low pressure. A primary instrument, it is often used as a standard for calibrating other instruments. The static, velocity, and total pressures in a duct system relative to the atmospheric pressure are measured with a pitot tube connected to a manometer. Pitot tube construction and locations for traversing round and rectangular ducts are presented in Chapter 13.

SYSTEM ANALYSIS

The friction and dynamic losses for each section of a duct system are calculated by Equation (14).

$$\Delta p_{t_i} = \Delta p_{f_i} + \sum_{j=1}^{m} \Delta p_{ij} + \sum_{k=1}^{n} \Delta p_{ik} - \sum_{r=1}^{\lambda} p_{se_{ir}},$$
$$i = 1, 2, \ldots, n_{up} + n_{dn} \tag{14}$$

where

Δp_{t_i} = net total pressure change for i-section, in. of water
Δp_{f_i} = pressure loss due to friction for i-section, in. of water
Δp_{ij} = total pressure loss due to j-fittings, including fan system effect (FSE), for i-section, in. of water
Δp_{ik} = pressure loss due to k-equipment for i-section, in. of water
$p_{se_{ir}}$ = stack effect due to r-stacks for i-section, in. of water
m = number of fittings within i-section
n = number of equipment within i-section
n_{dn} = number of duct sections downstream of fan (supply air subsystems)
n_{up} = number of duct sections upstream of fan (exhaust/return air subsystems)
λ = number of stacks within i-section

From Equation (7), the stack effect for each nonhorizontal duct with a density other than ambient air is determined by Equation (15).

$$p_{se} = 0.192\,(\rho_a - \rho)(z_2 - z_1) \tag{15}$$

where

p_{se} = stack effect, in. of water
z_1 and z_2 = elevation from datum in direction of airflow (Figure 1), ft
ρ_a = density of ambient air, lb_m/ft^3
ρ = density of air or gas within duct, lb_m/ft^3

The elevation/density pressure due to stack effect (p_{se}) can be positive or negative depending on whether it assists or resists airflow. As shown by Figure 1, an imaginary fan helps to explain buoyancy effects within systems. For flow upward and $\rho > \rho_a$ (Figure 1A) and flow downward and $\rho < \rho_a$ (Figure 1B), the excess pressure is negative and resists flow, thus increasing the fan total pressure requirement. On the other hand, for flow upward and $\rho < \rho_a$ (Figure 1C) and flow downward and $\rho > \rho_a$ (Figure 1D), the excess pressure is positive and assists flow, thus decreasing the fan total pressure requirement. To determine the fan total pressure requirement for a system, use Equation (16).

$$P_t = \sum_{i \in F_{up}} \Delta p_{t_i} + \sum_{i \in F_{dn}} \Delta p_{t_i},\ i = 1, 2, \ldots, n_{up} + n_{dn} \tag{16}$$

where F_{up} and F_{dn} are sets of duct sections upstream and downstream of a fan, and the symbol $\in$ ties the duct section into system paths from the exhaust/return air terminals to the supply terminals. Figure 2 illustrates the use of Equation (16). This system has three supply and two return terminals consisting of nine sections connected in six paths: 1-3-4-9-7-5, 1-3-4-9-7-6, 1-3-4-9-8, 2-4-9-7-5, 2-4-9-7-6, and 2-4-9-8. Sections 1 and 3 are unequal area; thus, they are assigned separate numbers in accordance with the rules for identifying sections (see the HVAC Duct Design Procedures section, step 4). To determine the fan pressure requirement, the following six equations, derived from Equation (16), are applied. These equations must be satisfied to attain pressure balancing for design airflow. Relying entirely on dampers is not economical and may create objectionable flow-generated noise.

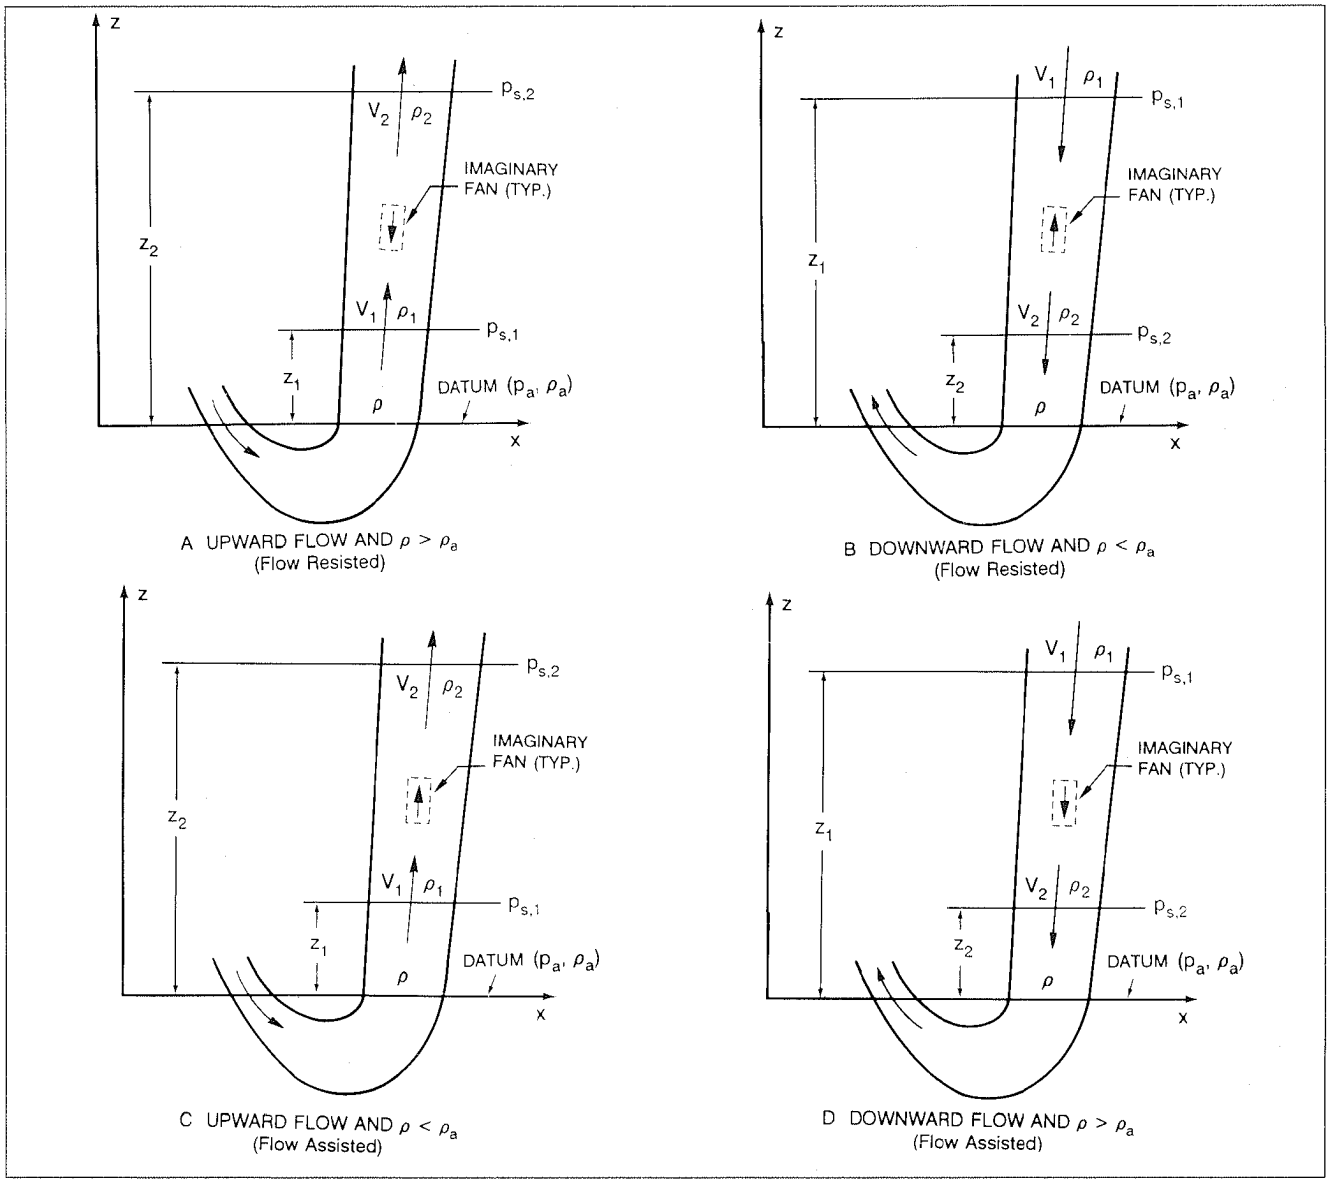

Fig. 1 Stack Effect Illustrations

$$\left.\begin{aligned} P_t &= \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t &= \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t &= \Delta p_1 + \Delta p_3 + \Delta p_4 + \Delta p_9 + \Delta p_8 \\ P_t &= \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_5 \\ P_t &= \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_7 + \Delta p_6 \\ P_t &= \Delta p_2 + \Delta p_4 + \Delta p_9 + \Delta p_8 \end{aligned}\right\} \quad (17)$$

where

P_t = fan total pressure, in. of water

Pressure Changes in System

Figure 3 shows total and static pressure changes in a fan/duct system consisting of a fan with both supply and return air ductwork. Also shown are the total and static pressure gradients referenced to atmospheric pressure.

For all constant-area sections, the total and static pressure losses are equal. At the diverging transitions, velocity pressure decreases, absolute total pressure decreases, and absolute static pressure can increase. The static pressure increase at these sections is known as *static regain*.

At the converging transitions, velocity pressure increases in the direction of airflow, and the absolute total and absolute static pressures decrease.

At the exit, the total pressure loss depends on the shape of the fitting and the flow characteristics. Exit loss coefficients C_o can be greater than, less than, or equal to one. The total and static pressure grade lines for the various coefficients are shown in Figure 3. Note that for a loss coefficient less than one, static pressure upstream of the exit is less than atmospheric pressure (negative). The static pressure just upstream of the discharge fitting can be calculated by subtracting the upstream velocity pressure from the upstream total pressure.

At section 1, the total pressure loss depends on the shape of the entry. The total pressure immediately downstream of the entrance

equals the difference between the upstream pressure, which is zero (atmospheric pressure), and the loss through the fitting. The static pressure of the ambient air is zero; several diameters downstream, static pressure is negative, algebraically equal to the total pressure (negative) and the velocity pressure (always positive).

System resistance to airflow is noted by the total pressure grade line in Figure 3. Sections 3 and 4 include fan system effect pressure losses. To obtain the fan static pressure requirement for fan selection where the fan total pressure is known, use:

$$P_s = P_t - p_{v,o} \tag{18}$$

where

P_s = fan static pressure, in. of water
P_t = fan total pressure, in. of water
$p_{v,o}$ = fan outlet velocity pressure, in. of water

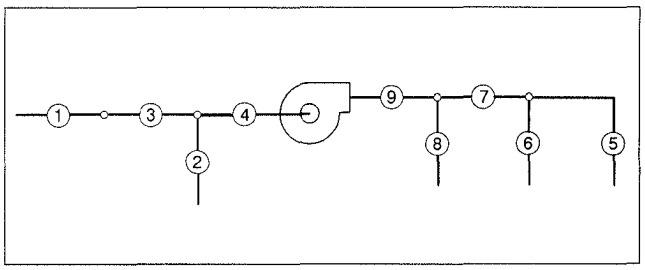

Fig. 2 Illustrative 6-Path, 9-Section System

FLUID RESISTANCE

Duct system losses are the irreversible transformation of mechanical energy into heat. The two types of losses are (1) frictional losses and (2) dynamic losses.

FRICTIONAL LOSSES

Frictional losses are due to fluid viscosity and are a result of momentum exchange between molecules in laminar flow and between particles moving at different velocities in turbulent flow. Frictional losses occur along the entire duct length.

Darcy, Colebrook, and Altshul Equations

For fluid flow in conduits, friction loss can be calculated by the Darcy equation:

$$\Delta p_f = f(12L/D_h)\,\rho\,(V/1097)^2 \tag{19}$$

where

Δp_f = friction losses in terms of total pressure, in. of water
f = friction factor, dimensionless
L = duct length, ft
D_h = hydraulic diameter [Equation (24)], in.
V = velocity, fpm
ρ = density, lb_m/ft^3

Within the region of laminar flow (Reynolds numbers less than 2000), the friction factor is a function of Reynolds number only.

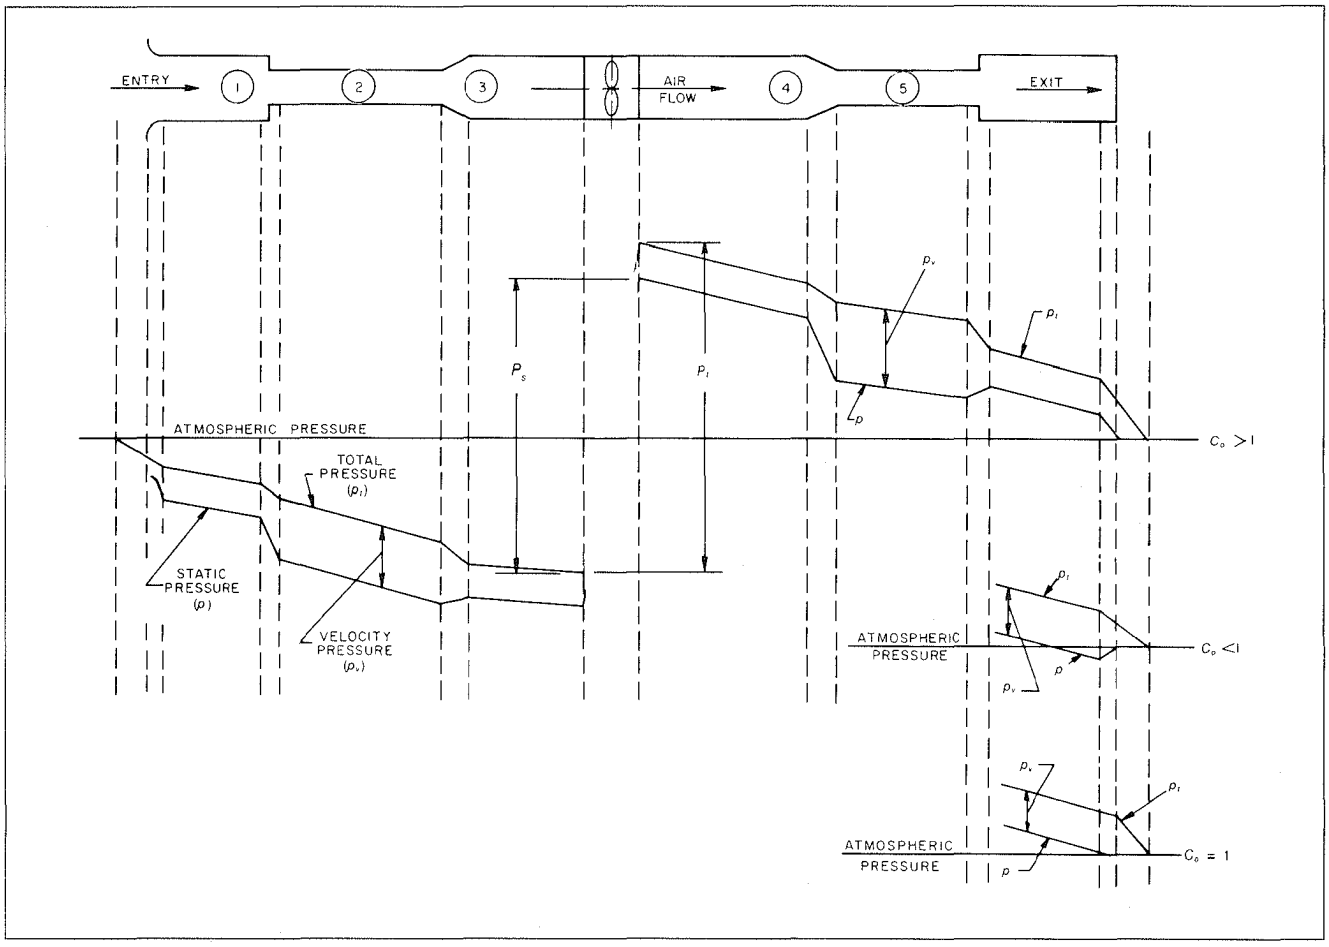

Fig. 3 Pressure Changes During Flow in Ducts

For turbulent flow, the friction factor depends on Reynolds number, duct surface roughness, and internal protuberances such as joints. The traditional Moody chart depicts the behavior for round passages. For hydraulically smooth ducts, the friction factor again depends only on Reynolds number, but the dependence is markedly different from that for laminar flow. In general, for nonsmooth surfaces, the friction factor depends on roughness and Reynolds number; however, for a particular level of roughness beyond a sufficiently large Reynolds number, the friction factor becomes independent of Reynolds number, a flow condition considered as fully rough. Between the bounding limits of hydraulically smooth behavior and fully rough behavior, is a transitional roughness zone where the friction factor depends on both roughness and Reynolds number. In this transitionally rough, turbulent zone, where most cases of airflow occur in air-conditioning applications, the friction factor f is calculated by Colebrook's equation (1938-39). Since this equation cannot be solved explicitly for f, use iterative techniques (Behls 1971).

$$\frac{1}{f^{0.5}} = -2\log\left[\frac{12\epsilon}{3.7D_h} + \frac{2.51}{\mathrm{Re}\,f^{0.5}}\right] \tag{20}$$

where

ϵ = material absolute roughness factor, ft
Re = Reynolds number

A simplified formula for calculating friction factor, developed by Altshul (1975) and modified by Tsal, is

$$f' = 0.11\left(\frac{12\epsilon}{D_h} + \frac{68}{\mathrm{Re}}\right)^{0.25}$$

$$\text{If } f' \geq 0.018: \quad f = f'$$

$$\text{If } f' < 0.018: \quad f = 0.85f' + 0.0028 \tag{21}$$

Friction factors obtained from Altshul's modified equation are within 1.6% of those obtained by Colebrook's equation.

Reynolds number (Re) may be calculated by using Equation (22).

$$\mathrm{Re} = \frac{D_h V}{720\,\nu} \tag{22}$$

where ν = kinematic viscosity, ft^2/s.

For standard air, Re can be calculated by

$$\mathrm{Re} = 8.56\,D_h V \tag{23}$$

Roughness Factors (ϵ)

The ϵ-values listed in Table 1 are recommended for use with the Colebrook or Altshul-Tsal equation. These values should be interpreted as representing a combination of material, duct construction, joint type, and joint spacing (Griggs and Khodabakhsh-Sharifabad 1992). Roughness factors for other materials are presented in Idelchik *et al.* (1986). Idelchik summarizes roughness factors for 80 materials including metal tubes; conduits made from concrete and cement; and wood, plywood, and glass tubes.

Swim (1978) conducted tests on duct liners of varying densities, surface treatments, transverse joints (workmanship), and methods of attachment to sheet metal ducts. As a result of these tests, Swim recommends for design 0.015 ft for spray-coated liners and 0.005 ft for liners with a facing material cemented onto the air side. In both cases, the roughness factor includes the resistance offered by mechanical fasteners and assumes good joints. Liners cut too long and fastened to the duct cause much more loss than a liner cut too short; therefore, any fabrication error in liner length should be on the short side. Liner density does not significantly influence flow resistance.

Manufacturers' data indicate that the absolute roughness for fully extended nonmetallic flexible ducts ranges from 0.0035 to 0.015 ft. For fully extended flexible metallic ducts, absolute roughness ranges from 0.0004 to 0.007 ft. This range covers flexible duct with the supporting wire exposed to flow or covered by the material. Figure 4 provides a pressure drop correction factor for straight flexible duct when less than fully extended.

Table 1 Duct Roughness Factors

Duct Material	Roughness Category	Absolute Roughness ϵ, ft
Uncoated carbon steel, clean (Moody 1944) (0.00015 ft)	Smooth	0.0001
PVC plastic pipe (Swim 1982) (0.00003 - 0.00015 ft)		
Aluminum (Hutchinson 1953) (0.000015 - 0.0002 ft)		
Galvanized steel, longitudinal seams, 4-ft joints (Griggs *et al.* 1987) (0.00016 - 0.00032 ft)	Medium smooth	0.0003
Galvanized steel, continuously rolled, spiral seams, 10-ft joints (Jones 1979) (0.0002 - 0.0004 ft)		
Galvanized steel, spiral seam with 1, 2, and 3 ribs, 12-ft joints (Griggs *et al.* 1987) (0.00029 - 0.00038 ft)		
Galvanized steel, longitudinal seams, 2.5-ft joints (Wright 1945) (0.0005 ft)	Average	0.0005
Fibrous glass duct, rigid	Medium	0.003
Fibrous glass duct liner, air side with facing material (Swim 1978) (0.005 ft)	Rough	
Fibrous glass duct liner, air side spray coated (Swim 1978) (0.015 ft)	Rough	0.01
Flexible duct, metallic (0.004 - 0.007 ft when fully extended)		
Flexible duct, all types of fabric and wire (0.0035 - 0.015 ft when fully extended)		
Concrete (Moody 1944) (0.001 - 0.01 ft)		

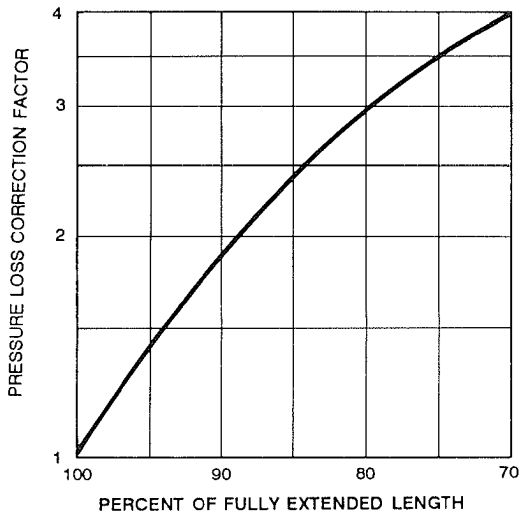

Fig. 4 Correction Factor for Unextended Flexible Duct

Friction Chart

Fluid resistance caused by friction in round ducts can be determined by the Friction Chart (Figure 5). This chart is based on standard air flowing through round galvanized ducts with beaded slip couplings on 48-in. centers, equivalent to an absolute roughness of 0.0003 ft.

Changes in barometric pressure, temperature, and humidity affect air density, air viscosity, and Reynolds number. No corrections to the Friction Chart are needed for (1) duct materials with a medium smooth roughness factor, (2) temperature variations in the order of ±30°F from 70°F, (3) elevations to 1500 ft, and (4) duct pressures from −20 in. of water to +20 in. of water relative to the ambient pressure. These individual variations in temperature, elevation, and duct pressure result in duct losses within ±5% of the standard air friction chart.

For duct materials other than those categorized as medium smooth in Table 1, and for variations in temperature, barometric pressure (elevation), and duct pressures (outside the range listed), calculate the pressure loss in a duct due to friction by the Altshul-Tsal and Darcy equations [(21) and (19), respectively].

Noncircular Ducts

A momentum analysis can relate average wall shear stress to pressure drop per unit length for fully developed turbulent flow in a passage of arbitrary shape but of uniform longitudinal cross-sectional area. Combining the result with the definition of the Darcy friction factor leads to Equation (24), with the ratio $4A/P$ defined as hydraulic diameter:

$$D_h = 4A/P \tag{24}$$

where

D_h = hydraulic diameter, in.
A = duct area, in^2
P = perimeter of cross section, in.

While the hydraulic diameter is often used to correlate noncircular data, exact solutions for laminar flow in noncircular passages show that such practice causes some inconsistencies. No exact solutions exist for turbulent flow. Tests over a limited range of turbulent flow indicated that fluid resistance is the same for equal lengths of duct for equal mean velocities of flow if the ducts have the same ratio of cross-sectional area to perimeter. From a series of experiments using round, square, and rectangular ducts having essentially the same hydraulic diameter, Huebscher (1948) found that each, for most purposes, had the same flow resistance at equal mean velocities. Tests by Griggs and Khodabakhsh-Sharifabad (1992) also indicated that experimental rectangular duct data for airflow over the range typical of HVAC systems can be correlated satisfactorily using Equation (20) together with hydraulic diameter, particularly when a realistic experimental uncertainty is accepted. These tests support using hydraulic diameter to correlate noncircular duct data.

Rectangular ducts. Huebscher developed the relationship between rectangular and round ducts that is used to determine size equivalency based on equal flow, resistance, and length. This relationship, Equation (25), is the basis for Table 2.

$$D_e = 1.30 \frac{(ab)^{0.625}}{(a+b)^{0.250}} \tag{25}$$

where

D_e = circular equivalent of rectangular duct for equal length, fluid resistance, and airflow, in.
a = length of one side of duct, in.
b = length of adjacent side of duct, in.

To size retangular ducts, determine the circular duct diameter by any design method, and use Table 2 to select the equivalent duct size as a function of aspect ratio. Equations (21) or (20) and (19) must be used to determine pressure loss.

Flat oval ducts. To convert round ducts to spiral flat oval sizes, use Table 3. Table 3 is based on Equation (26) (Heyt and Diaz 1975), the circular equivalent of a flat oval duct for equal airflow, resistance, and length. Equations (21) or (20) and (19) must be used to determine frictional pressure loss.

$$D_e = \frac{1.55\,A^{0.625}}{P^{0.250}} \tag{26}$$

where A is the cross-sectional area of flat oval duct defined as:

$$A = (\pi b^2/4) + b\,(a - b) \tag{27}$$

and the perimeter P is calculated by:

$$P = \pi b + 2(a - b) \tag{28}$$

where

P = perimeter of flat oval duct, in.
a = major dimension of flat oval duct, in.
b = minor dimension of flat oval duct, in.

DYNAMIC LOSSES

Dynamic losses result from flow disturbances caused by fittings that change the airflow path's direction and/or area. These fittings include entries, exits, transitions, and junctions. Idelchik (1986) discusses parameters affecting fluid resistance of fittings and presents loss coefficients in three forms: tables, curves, and equations.

Local Loss Coefficients

The following dimensionless coefficient is used for fluid resistance, since this coefficient has the same value in dynamically similar streams, *i.e.*, streams with geometrically similar stretches, equal values of Reynolds number, and equal values of other criteria necessary for dynamic similarity. The fluid resistance coefficient represents the ratio of total pressure loss to velocity pressure at the referenced cross section.

$$C = \frac{\Delta p_j}{\rho(V/1097)^2} = \frac{\Delta p_j}{p_v} \tag{29}$$

where

C = local loss coefficient, dimensionless
Δp_j = fitting total pressure loss, in. of water
ρ = density, lb$_m$/ft^3
V = velocity, fpm
p_v = velocity pressure, in. of water

Dynamic losses occur along a duct length and cannot be separated from frictional losses. For ease of calculation, dynamic losses are assumed to be concentrated at a section (local) and to exclude friction. Frictional losses must be considered only for relatively long fittings. Generally, fitting friction losses are accounted for by measuring duct lengths from the centerline of one fitting to that of the next fitting. For fittings closely coupled (less than six hydraulic diameters apart), the flow pattern entering subsequent fittings differs from the flow pattern used to determine loss coefficients. Adequate data for these situations are unavailable.

For all fittings, except junctions, calculate the total pressure loss Δp_j at a section by:

$$\Delta p_j = C_o\, p_{v,o} \tag{30}$$

where the subscript o is the cross section at which the velocity pressure is referenced. The dynamic loss is based on the actual velocity in the duct, not the velocity in an equivalent noncircular duct. For the cross section to reference a fitting loss coefficient, refer to step 4 of the HVAC Duct Design Procedures section. Where necessary (unequal area fittings), convert a loss coefficient from section o to section i by Equation (31), where V is the velocity at the respective sections.

$$C_i = \frac{C_o}{(V_i/V_o)^2} \tag{31}$$

For converging and diverging flow junctions, total pressure losses through the straight (main) section are calculated as:

$$\Delta p_j = C_{c,s}\, p_{v,c} \tag{32}$$

For total pressure losses through the branch section:

$$\Delta p_j = C_{c,b}\, p_{v,c} \tag{33}$$

where $p_{v,c}$ is the velocity pressure at the common section c, and $C_{c,s}$ and $C_{c,b}$ are losses for the straight (main) and branch flow paths, respectively, each referenced to the velocity pressure at section c. To convert junction local loss coefficients referenced to straight and branch velocity pressures, use Equation (34).

$$C_i = \frac{C_{c,i}}{(V_i/V_c)^2} \tag{34}$$

where

C_i = local loss coefficient referenced to section being calculated (see subscripts), dimensionless

$C_{c,i}$ = straight ($C_{c,s}$) or branch ($C_{c,b}$) local loss coefficient referenced to dynamic pressure at common section, dimensionless
V_i = velocity at section to which C_i is being referenced, fpm
V_c = velocity at common section, fpm

Subscripts:

b = branch
s = straight (main) section
c = common section

The junction of two parallel streams moving at different velocities is characterized by turbulent mixing of the streams, accompanied by pressure losses. In the course of this mixing, an exchange of momentum takes place between the particles moving at different velocities, finally resulting in the equalization of the velocity distributions in the common stream. The jet with higher velocity loses a part of its kinetic energy by transmitting it to the slower moving jet. The loss in total pressure before and after mixing is always large and positive for the higher velocity jet and increases with an increase in the amount of energy transmitted to the lower velocity jet. Consequently, the local loss coefficient, defined by Equation (29), will always be positive. The energy stored in the lower velocity jet increases as a result of mixing. The loss in total pressure and the local loss coefficient can, therefore, also have negative values for the lower velocity jet (Idelchik 1986).

Duct Fitting Database

A duct fitting database, developed by ASHRAE (1993), which includes 228 round and rectangular fittings with the provision to include flat oval fittings is available from ASHRAE in electronic form with the capability to be linked to duct design programs.

The fittings are numbered (coded) as shown in Table 4. Entries and converging junctions are only in the exhaust/return portion of systems. Exits and diverging junctions are only in supply systems. Equal-area elbows, obstructions, and duct-mounted equipment are common to both supply and exhaust systems. Transitions and unequal-area elbows can be either supply or exhaust fittings. Fitting ED5-1 (see Fitting Loss Coefficients section) is an Exhaust fitting with a round shape (Diameter). The number 5 indicates that the fitting is a junction, and 1 is its sequential number. Fittings SR3-1 and ER3-1 are Supply and Exhaust fittings, respectively. The R indicates that the fitting is Rectangular, and 3 identifies the fitting as an elbow. Note that the cross-sectional area at sections 0 and 1 are not equal. Otherwise, the elbow would be a Common fitting such as CR3-6. Additional fittings are reproduced in the Fitting Loss Coefficients section to support the example design problems. These fittings are identified by Tables 10 (Example 3) and 12 (Example 4).

Table 4 Duct Fitting Codes

Fitting Function	Geometry	Category	Sequential Number
S: Supply	D: round (Diameter)	1. Entries 2. Exits	1,2,3...n
E: Exhaust/ Return	R: Rectangular	3. Elbows 4. Transitions	
C: Common (supply and return)	O: flat Oval	5. Junctions 6. Obstructions 7. Fan and system interactions 8. Duct-mounted equipment 9. Dampers 10. Hoods 11. Straight duct	

DUCTWORK SECTIONAL LOSSES

Darcy-Weisbach Equation

Total pressure loss in a duct section is calculated by combining Equations (19) and (29) in terms of Δp, where ΣC is the summation of local loss coefficients within the duct section. Each fitting loss coefficient must be referenced to that section's velocity pressure.

$$\Delta p = \left(\frac{12fL}{D_h} + \Sigma C\right) \rho\,(V/1097)^2 \qquad (35)$$

FAN-SYSTEM INTERFACE

Fan Inlet and Outlet Conditions

Fan performance data measured in the field may show lower performance capacity than manufacturers' ratings. The most common causes of deficient performance of the fan/system combination are improper outlet connections, nonuniform inlet flow, and swirl at the fan inlet. These conditions alter the aerodynamic characteristics of the fan so that its full flow potential is not realized. One bad connection can reduce fan performance far below its rating. No data has been published that accounts for the effects of fan inlet and outlet flexible vibration connectors.

Normally, a fan is tested with open inlets and a section of straight duct attached to the outlet (ASHRAE 1985). This setup results in uniform flow into the fan and efficient static pressure recovery on the fan outlet. If good inlet and outlet conditions are not provided in the actual installation, the performance of the fan suffers. To select and apply the fan properly, these effects must be considered, and the pressure requirements of the fan, as calculated by standard duct design procedures, must be increased.

Figure 6 illustrates deficient fan/system performance. The system pressure losses have been determined accurately and a fan selected for operation at Point 1. However, no allowance has been made for the effect of system connections to the fan on fan performance. To compensate, a fan system effect must be added to the calculated system pressure losses to determine the actual system curve. The point of intersection between the fan performance curve and the actual system curve is Point 4. The actual flow volume is, therefore, deficient by the difference from 1 to 4. To achieve design flow volume, a fan system effect pressure loss

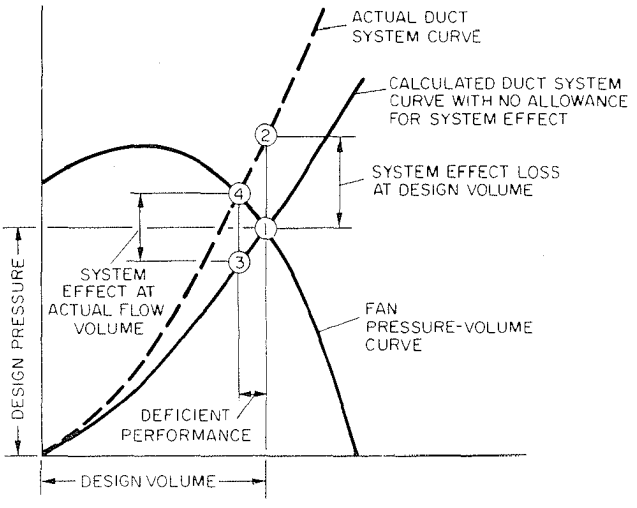

Fig. 6 Deficient System Performance with System Effect Ignored

equal to the pressure difference between Points 1 and 2 should be added to the calculated system pressure losses and the fan selected to operate at Point 2.

Fan System Effect Coefficients

The system effect concept was formulated by Farquhar (1973) and Meyer (1973); the magnitudes of the system effect, called *system effect factors*, were determined experimentally in AMCA's laboratory (Brown 1973, Clarke *et al.* 1978), and published in their *Fan Application Manual, Publication* 201 (1990a). The system effect factors, converted to system effect coefficients, are in the ASHRAE Duct Fitting Database (1993) for both centrifugal and axial fans. Fan system effect coefficients are only an approximation, however. Fans of different types and even fans of the same type, but supplied by different manufacturers, do not necessarily react to a system in the same way. Therefore, judgment based on experience must be applied to any design.

Fan outlet conditions. Fans intended primarily for duct systems are usually tested with an outlet duct in place (ASHRAE 1985b). Figure 7 shows the changes in velocity profiles at various distances from the fan outlet. For 100% recovery, the duct, including transition, must meet the requirements for 100% effective duct length [L_e (Figure 7)] which is calculated as follows:

$V_o > 2500$ fpm:

$$L_e = \frac{V_o A_o^{0.5}}{10{,}600} \tag{36}$$

$V_o \leq 2500$ fpm:

$$L_e = \frac{A_o^{0.5}}{4.3} \tag{37}$$

where

V_o = duct velocity, fpm
L_e = effective duct length, ft
A_o = duct area, in^2

As illustrated by Fitting SR7-1 in the Fitting Loss Coefficients section, centrifugal fans should not abruptly discharge to the atmosphere. A diffuser design should be selected from Fitting SR7-2 or SR7-3 (ASHRAE 1993).

Fan inlet conditions. For rated performance, air must enter the fan uniformly over the inlet area in an axial direction without prerotation. Nonuniform flow into the inlet is the most common cause of reduced fan performance. Such inlet conditions are not equivalent to a simple increase in the system resistance; therefore, they cannot be treated as a percentage decrease in the flow and pressure from the fan. A poor inlet condition results in an entirely new fan performance. Many poor inlet conditions affect the fan more at near-free delivery conditions than at peak pressure, so there is a continually varying difference between these two points. An elbow at the fan inlet, for example Fitting ED7-2, causes turbulence and uneven flow into the fan impeller. The losses due to the fan system effect can be eliminated by including an adquate length of straight duct between the elbow and the fan inlet.

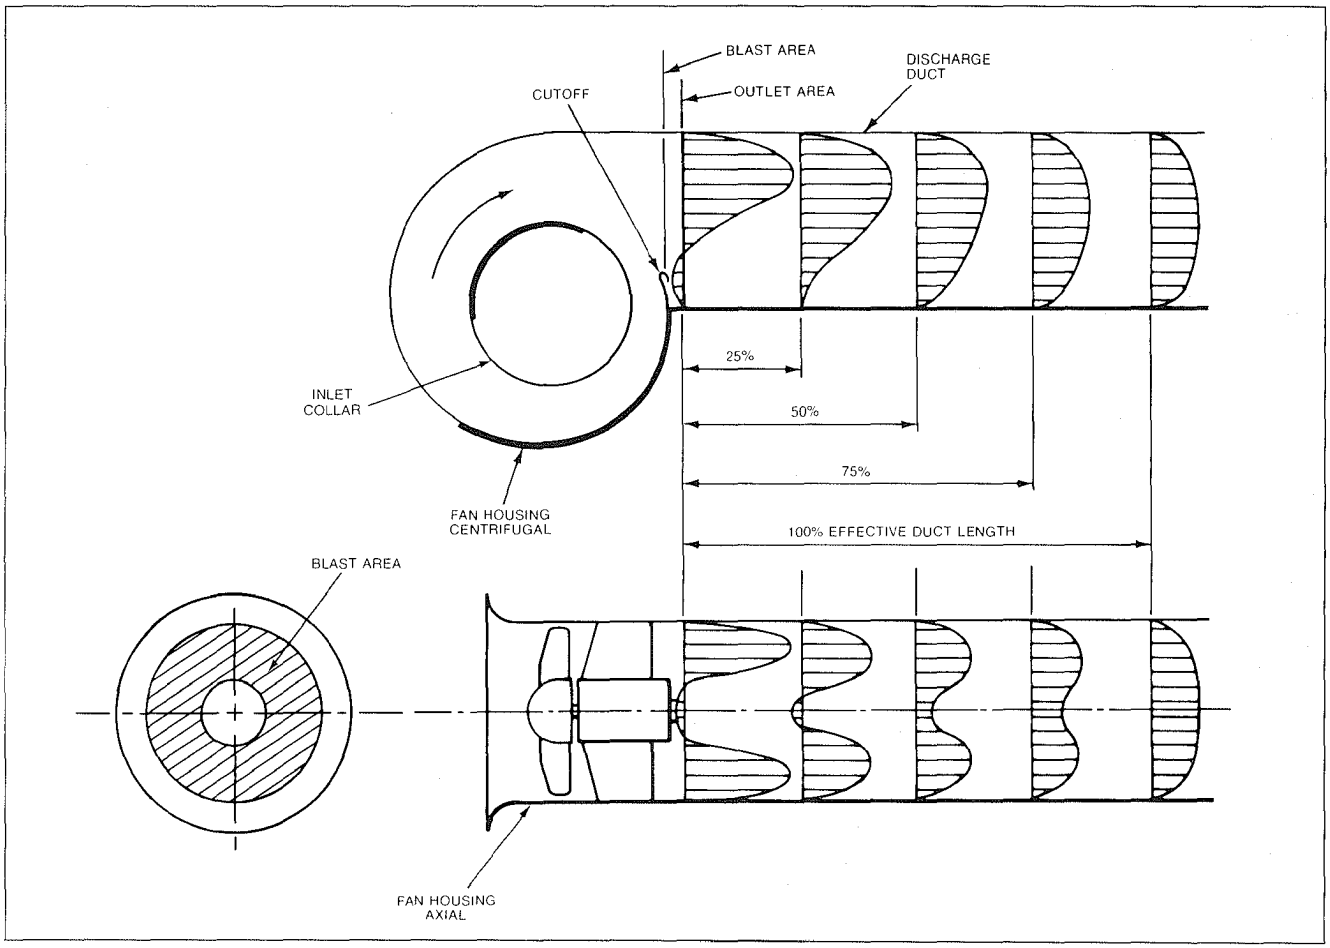

Fig. 7 Establishment of Uniform Velocity Profile in Straight Fan Outlet Duct
(Adapted by permission from AMCA Publication 201)

The ideal inlet condition allows air to enter axially and uniformly without spin. A spin in the same direction as the impeller rotation reduces the pressure-volume curve by an amount dependent on the intensity of the vortex. A counterrotating vortex at the inlet slightly increases the pressure-volume curve, but the power is increased substantially.

Inlet spin may arise from a great variety of approach conditions, and sometimes the cause is not obvious. Inlet spin can be avoided by providing an adequate length of straight duct between the elbow and the fan inlet. Figure 8 illustrates some common duct connections that cause inlet spin and includes recommendations for correcting spin.

Fans within plenums and cabinets or next to walls should be located so that air may flow unobstructed into the inlets. Fan performance is reduced if the space between the fan inlet and the enclosure is too restrictive. The system effect coefficients for fans in an enclosure or adjacent to walls are listed under Fitting ED7-1. The manner in which the airstream enters an enclosure in relation to the fan inlets also affects fan performance. Plenum or enclosure inlets or walls that are not symmetrical with the fan inlets cause uneven flow and/or inlet spin.

TAB Considerations

Fan system effects (FSEs) are not only to be used in conjunction with the system resistance characteristics in the fan selection process, but are also applied in the calculations of the results of testing, adjusting, and balancing (TAB) field tests to allow direct comparison to design calculations and/or fan performance data. Fan inlet swirl and the effect of poor fan inlet and outlet ductwork connections on system performance cannot be measured directly. Poor inlet flow patterns affect fan performance within the impeller wheel (centrifugal fan) or wheel rotor impeller (axial fan), while the fan outlet system effect is flow instability and turbulence within the fan discharge ductwork.

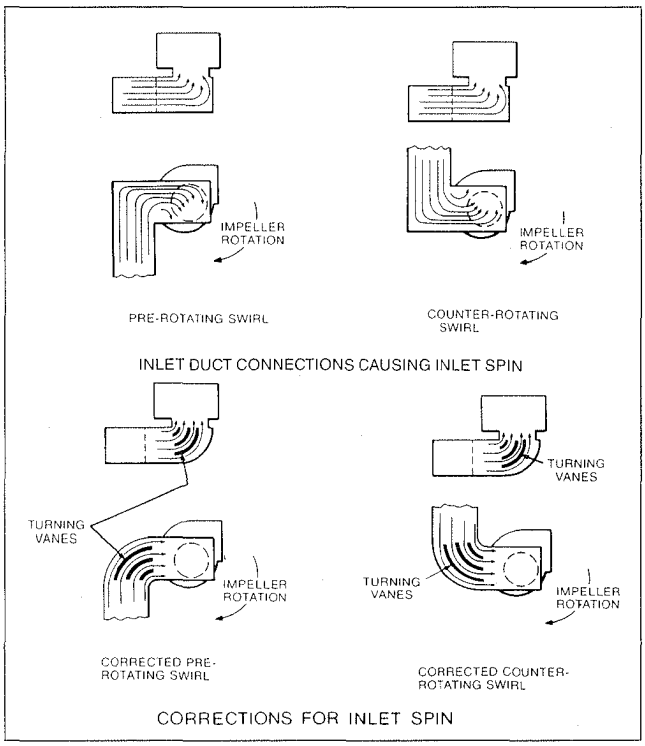

Fig. 8 Inlet Duct Connections Causing Inlet Spin and Corrections for Inlet Spin
(Adapted by permission from AMCA Publication 201)

The static pressure at the fan inlet and the static pressure at the fan outlet may be measured directly in some systems. In most cases, static pressure measurements for use in determining fan total (or static) pressure will not be made directly at the fan inlet and outlet, but at locations a relatively short distance from the fan inlet and downstream from the fan outlet. To calculate fan total pressure for this case from field measurements, use Equation (38), where $\Delta p_{x\text{-}y}$ is the summation of calculated total pressure losses between the fan inlet and outlet sections noted. If necessary, use Equation (18) to calculate fan static pressure knowing fan total pressure. For locating measurement planes and calculation procedures, consult AMCA Publication 203 (1990b).

$$P_t = (p_{s,5} + p_{v,5}) + \Delta p_{2\text{-}5} + \mathrm{FSE}_2 + (p_{s,4} + p_{v,4}) + \Delta p_{4\text{-}1} + \mathrm{FSE}_1 + \mathrm{FSE}_{1,s} \qquad (38)$$

where

P_t = fan total pressure, in. of water
p_s = static pressure, in. of water
p_v = velocity pressure, in. of water
FSE = fan system effect, in. of water
$\Delta p_{x\text{-}y}$ = summarization of total pressure losses between planes x and y, in. of water

Subscripts:

1 = fan inlet
2 = fan outlet
4 = plane of static pressure measurement upstream of fan
5 = plane of static pressure measurement downstream of fan
s = swirl

DUCT DESIGN CONSIDERATIONS

Space Pressure Relationships

Space pressure is determined by fan location and duct system arrangement. For example, a supply fan that pumps air into a space increases space pressure; an exhaust fan reduces space pressure. If both supply and exhaust fans are used, space pressure depends on the relative capacity of the fans. Space pressure is positive if supply exceeds exhaust; negative, if exhaust exceeds supply (Osborne 1966). System pressure variations due to wind can be minimized or eliminated by careful selection of intake air and exhaust vent locations (Chapter 14).

Fire and Smoke Control

Since duct systems can convey smoke, hot gases, and fire from one area to another and can accelerate a fire within the system, fire protection is an essential part of air-conditioning and ventilation system design. Generally, fire safety codes require compliance with the standards of national organizations. NFPA *Standard* 90A examines fire safety requirements for (1) ducts, connectors, and appurtenances; (2) plenums and corridors; (3) air outlets, air inlets, and fresh air intakes; (4) air filters; (5) fans; (6) electric wiring and equipment; (7) air cooling and heating equipment; (8) building construction, including protection of penetrations; and (9) controls, including smoke control.

Fire safety codes often refer to the testing and labeling practices of nationally recognized laboratories, such as Factory Mutual and Underwriters Laboratories (UL). The *Building Materials Directory* compiled by UL lists fire and smoke dampers that have been tested and meet the requirements of UL *Standards* 555 (1990) and 555S (1983). This directory also summarizes maximum allowable sizes for individual dampers and assemblies of these dampers. Fire dampers are 1.5 or 3-h fire-rated. Smoke dampers are classified

by (1) temperature degradation [ambient air or high temperature (250°F minimum)] and (2) leakage at 1 in. of water and 4 in. of water pressure difference (8 in. of water and 12 in. of water classification optional). Smoke dampers are tested under conditions of maximum airflow. UL's *Fire Resistance Directory* lists the fire resistance of floor/roof and ceiling assemblies with and without ceiling fire dampers.

For a more detailed presentation of fire protection, see Chapter 47 of the 1991 ASHRAE *Handbook—Applications* and the NFPA *Fire Protection Handbook* (1991).

Duct Insulation

All new construction (except low-rise residential buildings) air-handling ducts and plenums installed as part of an HVAC air distribution system should be thermally insulated in accordance with Section 9.4 of ASHRAE *Standard* 90.1 (1989). Additional insulation, vapor retarders, or both may be required to limit vapor transmission and condensation. Accessible ducts, plenums, and enclosures located in high-rise residential buildings (ASHRAE *Standard* 100.2), commercial buildings (ASHRAE *Standard* 100.3), industrial buildings (ASHRAE *Standard* 100.4), institutional buildings (ASHRAE *Standard* 100.5), and public assembly buildings (ASHRAE *Standard* 100.6) should also be thermally insulated in accordance with ASHRAE *Standard* 90.1.

Duct heat gains or losses must be known to calculate supply air quantities, supply air temperatures, and coil loads (see Chapter 26 of this volume and Chapter 2 of the 1992 ASHRAE *Handbook—Systems and Equipment*). To estimate duct heat transfer and entering or leaving air temperatures, use Equations (39) through (41).

$$Q_l = \frac{UPL}{12}\left[\left(\frac{t_e + t_l}{2}\right) - t_a\right] \tag{39}$$

$$t_e = \frac{t_l(y + 1) - 2t_a}{(y - 1)} \tag{40}$$

$$t_l = \frac{t_e(y - 1) + 2t_a}{(y + 1)} \tag{41}$$

where

y = $2.4AV\rho/UPL$ for rectangular ducts
y = $0.6DV\rho/UL$ for round ducts
A = cross-sectional area of duct, in^2
V = average velocity, fpm
D = diameter of duct, in.
L = duct length, ft
Q_l = heat loss/gain through duct walls, Btu/h (negative for heat gain)
U = overall heat transfer coefficient of duct wall, Btu/(h·ft^2·°F)
P = perimeter of bare or insulated duct, in.
ρ = density, lb$_m$/ft^3
t_e = temperature of air entering duct, °F
t_l = temperature of air leaving duct, °F
t_a = temperature of air surrounding duct, °F

Use Figure 9A to determine U-factors for insulated and uninsulated ducts. Lauvray (1978) has shown the effects of (1) compressing insulation wrapped externally on sheet metal ducts and (2) insulated flexible ducts with air porous liners. For a 2-in. thick, 0.75 lb/ft^3 fibrous glass blanket compressed 50% during installation, the heat transfer rate increases approximately 20% (see Figure 9A). Pervious flexible duct liners also influence heat transfer significantly (see Figure 9B). At 2500 fpm, the pervious liner U-value is 0.33 Btu/(h·ft^2·°F); for an impervious liner, 0.19 Btu/(h·ft^2·°F).

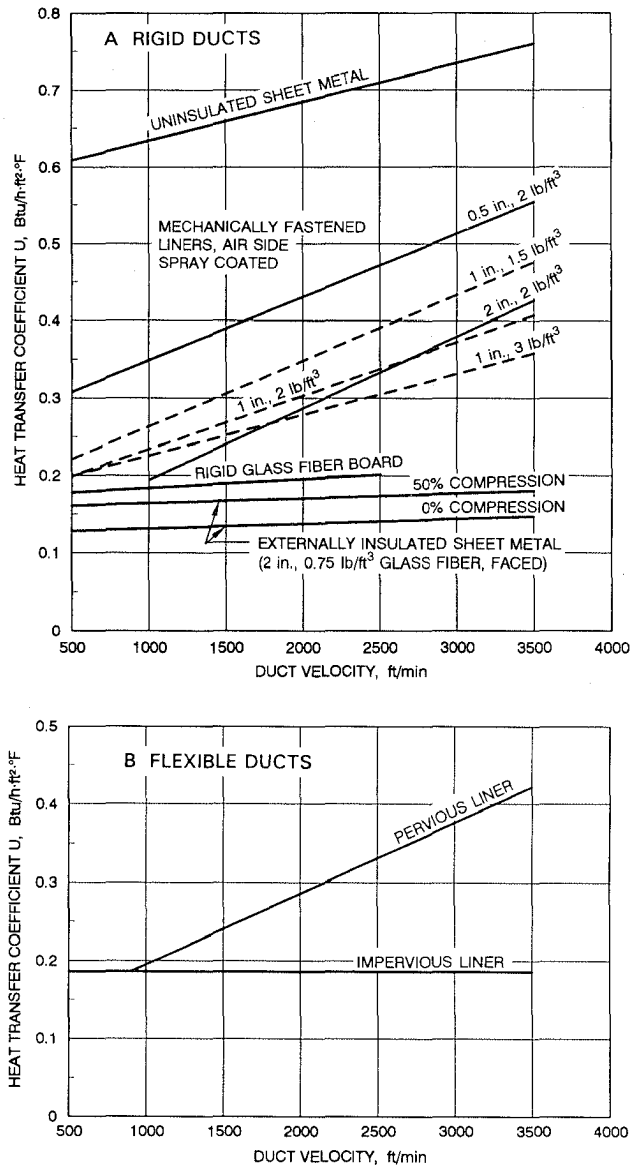

Fig. 9 Duct Heat Transfer Coefficients

Example 1. A 65-ft length of 24 in. by 36 in. uninsulated sheet metal duct, freely suspended, conveys heated air through a space maintained above freezing at 40°F. Based on heat loss calculations for the heated zone, 17,200 cfm of standard air at a supply air temperature of 122°F is required. The duct is connected directly to the heated zone. Determine the air temperature entering the duct and the duct heat loss.

Solution: Calculate duct velocity using Equation (10):

$$V = \frac{(144)\ (17{,}200\ \text{cfm})}{(24\ \text{in.})\ (36\ \text{in.})} = 2900\ \text{fpm}$$

Calculate entering air temperature using Equation (40):

U = 0.73 Btu/(h·ft^2·°F) (from Figure 9A)

P = 2(24 in. + 36 in.) = 120 in.

$$y = \frac{(2.4)\ (24\ \text{in.})\ (36\ \text{in.})\ (2900\ \text{fpm})\ (0.075\ \text{lb}_m/\text{ft}^3)}{(0.73\ \text{Btu/h}\cdot\text{ft}^2\cdot{}^\circ\text{F})\ (120\ \text{in.})\ (65\ \text{ft})} = 79.2$$

$$t_e = \frac{122°F\,(79.2 + 1) - (2 \times 40°F)}{(79.2 - 1)} = 124.1°F$$

Calculate duct heat loss using Equation (39):

$$Q_l = \frac{[0.73\ \text{Btu/(h·ft}^2\text{·°F)}]\ (120\ \text{in.})\ (65\ \text{ft})}{12} \times \left[\frac{124.1°F + 122°F}{2} - 40°F\right]$$

$$= 39{,}200\ \text{Btu/h}$$

Example 2. Same as Example 1, except the duct is insulated externally with 2 in. thick fibrous glass with a density of 0.75 lb/ft^3. The insulation is wrapped with 0% compression.

Solution: All values, except U and P, remain the same as Example 1. From Figure 9A, U = 0.15 Btu/(h·ft^2·°F) at 2900 fpm. P = 136 in. Therefore:

$$y = 441$$
$$t_e = 122.4°F$$
$$Q_l = 9083\ \text{Btu/h}$$

Insulating this duct reduces heat loss to 20% of the uninsulated duct.

Duct System Leakage

Leakage in all unsealed ducts varies considerably with the fabricating machinery used, the methods for assembly, and installation workmanship. For sealed ducts, a wide variety of sealing methods and products exists. Each has a relatively short shelf life, and no documented research has identified the in-service aging characteristics of sealant applications. Many sealants contain volatile solvents that evaporate and introduce shrinkage and curing factors. Surface cleanliness and sealant application in relation to air pressure direction (infiltration and exfiltration) are other variables. With the exception of pressure-sensitive adhesive tapes, no standard tests exist to evaluate performance and grade sealing products. A variety of sealed and unsealed duct leakage tests (AISI/SMACNA 1972, ASHRAE/SMACNA/TIMA 1985, ASHRAE 1988) have confirmed that longitudinal seam, transverse joint, and assembled duct leakage can be represented by Eqation (42), and that for the same construction leakage is not significantly different in the negative and positive modes. A range of leakage rates for longitudinal seams commonly used in the construction of metal ducts is presented in Table 5. Longitudinal seam leakage for metal ducts is about 10 to 15% of total duct leakage.

$$Q = C\,\Delta p_s{}^N \tag{42}$$

where

Q = duct leakage rate, cfm
C = constant reflecting area characteristics of leakage path
Δp_s = static pressure differential from duct interior to exterior
N = exponent relating turbulent or laminar flow in leakage path

Table 5 Unsealed Longitudinal Seam Leakage, Metal Ducts

Type of Duct/Seam	Leakage[a], cfm/ft (Seam Length) Range	Average
Rectangular		
Pittsburgh lock	0.01 to 0.56	0.16
Button punch snaplock	0.01 to 0.16	0.08
Round		
Snaplock	0.04 to 0.14	0.11
Grooved	0.11 to 0.18	0.12

[a]Leakage rate is at 1 in. of water static pressure.

Analysis of the AISI/ASHRAE/SMACNA/TIMA data resulted in the categorization of duct systems into a *leakage class* C_L based on Equation (43), where the exponent N is assumed to be 0.65. A selected series of leakage classes based on Equation (43) is shown in Figure 10.

$$C_L = Q/\Delta p_s{}^{0.65} \tag{43}$$

where

Q = leakage rate, cfm/100 ft^2 (surface area)
C_L = leakage class, cfm per 100 ft^2 duct surface at 1 in. of water static pressure

Table 6 is a summary of the leakage class attainable for quality duct construction and sealing practices. Connections of ducts to grilles, diffusers, and registers are not represented in the test data. The designer is responsible for assigning acceptable leakage rates. Although leakage as a percentage of fan flow rate is an important evaluation criterion (see Table 7), designers should first become familiar with the leakage rates from selected construction detail. This knowledge allows the designer to analyze both first cost and life cycle cost of a duct system so that the owner may benefit. In performing an analysis, the designer should independently account for air leakage in casings and frames of equipment in the duct system. Casings or volume-controlling air terminal units may leak 2 to 5% of their maximum flow. The effects of such leakage should be anticipated, if allowed, and the ductwork should not be expected to compensate for equipment leakage. Allowable leakage should be controlled consistent with airflow tolerances at the air terminals (see Chapter 34 of the 1991 ASHRAE *Handbook—Applications*). A leakage class of 3 is attainable for all duct systems by careful selection of joints and sealing methods and by good workmanship. Where less leakage is required, designers should understand that less experienced contractors may have difficulty meeting their requirements. Zero leakage is not a practical objective, except in critical situations such as nuclear safety-related applications. For additional discussion of leakage analysis, consult the HVAC *Air Duct Leakage Test Manual* (SMACNA 1985).

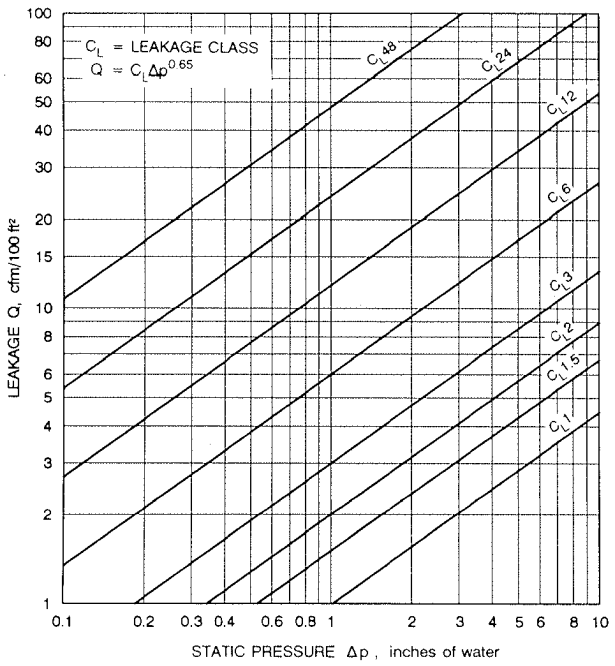

Fig. 10 Duct Leakage Classifications
[Adapted with permission from HVAC *Air Duct Leakage Test Manual* (SMACNA 1985)]

Energy loss via duct leakage is a serious concern. It is also of special importance in systems serving clean rooms, solar energy air collectors, industrial processes, and moisture removal applications. Sealing criteria appropriate for each special application should be specified by the designer. All new construction (except low-rise residential buildings) ductwork designed to operate at static pressures in excess of 3 in. of water should be, or may be required by code to be leak tested in accordance with Section 9.4 of ASHRAE *Standard* 90.1 (1989). Allowable leakage shall also be in compliance with ASHRAE *Standard* 90.1. Pressure-sensitive tape shall not be used as the primary sealant where such ducts are designed to operate at static pressures of 1 in. of water or greater. Soldered or welded duct construction is necessary where sealants are not suitable.

Shaft and compartment pressure changes affect duct leakage and are important to health and safety in the design and operation of contaminant and smoke control systems. Airflow around buildings, building component leakage, and the distribution of inside and outside pressures over the height of a building, including shafts, are discussed in Chapters 14 and 22. Smoke control system design is covered in Chapter 47 of the 1991 ASHRAE *Handbook—Applications* and in Klote and Milke (1992).

System Component Design Velocities

Table 8 summarizes face velocities for HVAC components in built-up systems. In most cases, the values are abstracted from pertinent chapters in the 1992 ASHRAE *Handbook—Systems and Equipment*; final selection of the components should be based on data in these chapters or from manufacturers.

Louvers require special treatment since the blade shapes, angles, and spacing cause significant variations in louver-free area and performance (pressure drop and water penetration). Selection and analysis should be based on test data obtained in accordance with AMCA *Standard* 500 (1989). This standard presents not only the pressure drop and water penetration test procedures, but a uniform method for calculating louver-free area. Tests are conducted on a 48-in. square louver with the frame mounted flush in the wall. For the water penetration tests, the rainfall is 4 in/h, no wind, and the water flow down the wall is 0.25 gpm per linear foot of louver width.

Use Figure 11 for preliminary sizing of air intake and exhaust louvers. For air quantities greater than 7000 cfm per louver, the air intake gross louver openings are based on 400 fpm; for exhaust louvers, 500 fpm is used for air quantities of 5000 cfm per louver and greater. For air quantities less than these, refer to Figure 11.

Table 6 Duct Leakage Classification[a]

Type Duct	Predicted Leakage Class C_L Sealed[b, c]	Unsealed[c]
Metal (flexible excluded)		
Round and flat oval	3	30 (6 to 70)
Rectangular		
≤ 2 in. of water (both positive and negative pressures)	12	48 (12 to 110)
> 2 and ≤ 10 in. of water (both positive and negative pressures)	6	48 (12 to 110)
Flexible		
Metal, Aluminum	8	30 (12 to 54)
Nonmetal	12	30 (4 to 54)
Fibrous glass		
Rectangular	6	NA
Round	3	NA

[a]The *leakage classes* listed in this table are averages based on tests conducted by AISI/SMACNA (1972), ASHRAE/SMACNA/TIMA (1985), and ASHRAE (1988). Leakage classes listed are not necessarily recommendations on allowable leakage. The designer should determine allowable leakage and specify acceptable duct leakage classifications.

[b]The *leakage classes* listed in the sealed category are based on the assumptions that for metal ducts, all transverse joints, seams, and openings in the ductwall are sealed at pressures over 3 in. of water, that transverse joints and longitudinal seams are sealed at 2 and 3 in. of water, and that transverse joints are sealed below 2 in. of water. Lower leakage classes are obtained by careful selection of joints and sealing methods.

[c]*Leakage classes* assigned anticipate about 25 joints per 100 linear foot of duct. For systems with a high fitting to straight duct ratio, greater leakage occurs in both the sealed and unsealed conditions.

Table 7 Leakage as Percentage of Airflow[a,b]

Leakage Class	System cfm/ft² Duct Surface[c]	Static Pressure, in. of water 0.5	1	2	3	4	6
48	2	15	24	38	49	59	77
	2.5	12	19	30	39	47	62

	5	0.1	0.2	0.3	0.3	0.4	0.5

[a]Adapted with permission from HVAC *Air Duct Leakage Test Manual* (SMACNA 1985, Appendix A).

[b]Percentage applies to the airflow entering a single section of duct operating at an assumed pressure equal to the average of the upstream and downstream pressures. When several duct pressure classifications occur in a system, ductwork in each pressure class should be evaluated independently to arrive at an aggregate leakage for the system.

[c]The ratios in this column are typical of fan volume flow rate divided by total system surface. Portions of the systems may vary from these averages.

Table 8 Typical Design Velocities for HVAC Components

Duct Element	Face Velocity, fpm
LOUVERS[a]	
Intake	
7000 cfm and greater	400
Less than 7000 cfm	See Fig. 11
Exhaust	
5000 cfm and greater	500
Less than 5000 cfm	See Fig. 11
FILTERS[b]	
Panel filters	
Viscous impingement	200 to 800
Dry-type, extended-surface	
Flat (low efficiency)	Duct Velocity
Pleated media (intermediate efficiency)	Up to 750
HEPA	250
Renewable media filters	
Moving-curtain viscous impingement	500
Moving-curtain dry-media	200
Electronic air cleaners	
Ionizing type	150 to 350
HEATING COILS[c]	
Steam and hot water	500 to 1000 200 min., 1500 max.
Electric	
Open wire	Refer to mfg. data
Finned tubular	Refer to mfg. data
DEHUMIDIFYING COILS[d]	400 to 500
AIR WASHERS[e]	
Spray type	300 to 600
Cell type	Refer to mfg. data
High-velocity, Spray type	1200 to 1800

Parameters Used to Establish Figure	Intake Louver	Exhaust Louver
Minimum free area (48-in. square test section), %	45	45
Water penetration, oz/(ft² · 0.25 h)	Negligible (less than 0.2)	NA
Maximum static pressure drop, in. of water	0.15	0.25

Fig. 11 Criteria for Louver Sizing

These criteria are presented on a per louver basis (*i.e.*, each louver in a bank of louvers) to include each louver frame. Representative production-run louvers were used in establishing Figure 11, and all data used in that analysis are based on AMCA standard tests. For louvers larger than 16 ft², the free areas are greater than 45%, while for louvers less than 16 ft², the free areas are less than 45%. Unless specific louver data are analyzed, no louver should have a face area less than 4 ft². If debris collection on the screen of an intake louver is possible, or if louvers are located at grade with adjacent pedestrian traffic, louver face velocity should not exceed 100 fpm.

System and Duct Noise

The major sources of noise from air-conditioning systems are diffusers, grilles, fans, ducts, fittings, and vibrations. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* discusses sound control for each of these sources. Sound control for terminal devices consists of selecting devices that meet the design goal under all operating conditions and installing them properly so that no additional sound is generated. The sound power output of a fan is determined by the type of fan, airflow, and pressure. Sound control in the duct system requires proper duct layout, sizing, and provision for installing duct attenuators, if required. The noise generated by a system increases with both duct velocity and system pressure. Chapter 42 of the 1991 ASHRAE *Handbook—Applications* presents methods for calculating required sound attenuation.

Testing and Balancing

Each air duct system should be tested, adjusted, and balanced. Detailed procedures are given in Chapter 34 of the 1991 ASHRAE *Handbook—Applications.* To properly determine fan total (or static) pressure from field measurements taking into account fan system effect, refer to the Fan-System Interface section. Equation (38) allows direct comparison of system resistance to design calculations and/or fan performance data. It is important that the system effect magnitudes be known prior to testing. If necessary, use Equation (18) to calculate fan static pressure knowing fan total pressure [Equation (38)]. For TAB calculation procedures of numerous fan/system configurations encountered in the field, refer to AMCA Publication 203 (1990b).

DUCT DESIGN METHODS

Duct design methods for HVAC systems, and exhaust systems conveying vapors, gases, and smoke are *equal friction, static regain,* and the *T-method.* The Industrial Exhaust System Duct Design section presents the design criteria and procedures for exhaust systems conveying particulates. Equal friction and static regain are nonoptimizing methods, while the T-method is a practical optimization method introduced by Tsal (1988).

To assure that system designs are acoustically acceptable, noise generation should be analyzed and sound attenuators and/or

acoustically lined duct provided where necessary. Dampers must be installed throughout systems designed by equal friction, static regain, and the T-method, since inaccuracies are introduced into these design methods by duct size round-off and the effect on the total pressure loss calculations by close-coupled fittings.

Equal Friction Method

In the equal friction method, ducts are sized for a constant pressure loss per unit length. The shaded area of the friction chart (Figure 5) is the suggested range of friction rate and air velocity. When energy cost is high and installed duct work cost is low, a low friction rate design is more economical. For low energy cost and high duct cost, a higher friction rate is more economical. After initial sizing, calculate the total pressure loss for all duct sections, then resize sections to balance pressure losses at each junction.

Static Regain Method

The objective of the static regain method is to obtain the same static pressure at diverging flow junctions by changing downstream duct sizes. This design objective can be developed by rearranging Equation (7) and setting p_2 equal to p_1 (neglect stack effect term). Thus

$$p_1 - p_2 = \Delta p - \left[\frac{\rho V_1^2}{2g_c} - \frac{\rho V_2^2}{2g_c}\right] \tag{44}$$

and

$$\Delta p = \frac{\rho V_1^2}{2g_c} - \frac{\rho V_2^2}{2g_c} \tag{45}$$

where Δp is the total pressure loss from upstream of junction 1 to upstream of junction 2, or the terminal of section 2. Since Δp can be calculated, the immediate downstream duct size that satisfies Equation (45) is determined by iteration. Equation (45) can be solved only when the downstream velocity is reduced, which may require the downstream duct size to be greater than the upstream duct. If this solution is undesirable, Equation (44) may be used by maintaining the same duct size downstream as upstream to solve for the static pressure at the next junction.

To start the design of a system, a maximum velocity is selected for the root section (duct section upstream and/or downstream of a fan). In Figure 13, section 6 is the root for the return air subsystem. Section 19 is the root for the supply air subsystem. The shaded area on the friction chart (Figure 5) is the suggested range of air velocity. When energy cost is high and installed ductwork cost is low, a lower initial velocity is more economical. For low energy cost and high duct cost, a higher velocity is more economical. All other sections, except terminal sections, are sized iteratively by Equation (45). In Figure 13, terminal sections are 1, 2, 4, 7, 8, 11, 12, 15, and 16. Knowing the terminal static pressure requirements, Equation (44) is used to calculate the duct size of terminal sections. If the terminal is an exit fitting rather than a register, diffuser, or terminal box, the static pressure at the exit of the terminal section is zero.

The classical static regain method (Carrier 1960, Chun-Lun 1983, Shataloff 1966) is based on Equation (46), where R is the static pressure regain factor, and Δp_r is the static pressure regain between junctions.

$$\Delta p_r = R\left[\frac{\rho V_1^2}{2g_c} - \frac{\rho V_2^2}{2g_c}\right] \tag{46}$$

Typically R-factors ranging from 0.5 to 0.95 have been used. Tsal and Behls (1988) show that this uncertainty results because the splitting of mass at junctions and the dynamic (fitting) losses between junctions are ignored. The classical static regain method using an R-factor should not be used since R is not predictable.

T-Method, Optimization

T-method optimization (Tsal *et al.* 1988) is a procedure based on the same tee-staging idea as dynamic programming (Bellman 1957). However, phase level vector tracing is eliminated by optimizing locally at each stage. This modification reduces the number of calculations, but requires iteration. Usually, three iterations are sufficient.

Optimization basis. The objective function, Equation (47), includes both initial system cost and the present worth of energy. Hours of operation, annual escalation and interest rates, and amortization period are also required for optimization.

$$E = E_p\,(\text{PWEF}) + E_s \tag{47}$$

where

E = present worth owning and operating cost
E_p = first year energy cost
E_s = initial cost
PWEF = present worth escalation factor (Smith 1968), dimensionless

Energy cost is determined by

$$E_p = Q_f\left[\frac{1.176 \times 10^4\,(E_d + E_c\,T)}{\eta_f\,\eta_e}\right] P_t \tag{48}$$

where

Q_f = fan airflow rate, cfm
E_c = unit energy cost, cost/kWh
E_d = energy demand cost, cost/kW
T = system operating time, h/year
P_t = fan total pressure, in. of water
η_f = fan total efficiency, decimal
η_e = motor-drive efficiency, decimal

Energy cost depends on both applicable energy rates E_c and demand cost E_d. Since the difference between the fan pressures for an optimized and nonoptimized system is a small part of demand, it is usually neglected. Initial cost includes ducts and HVAC equipment, which is primarily the central handling unit. The cost of duct systems is given by the following equations:

Round
$$E_s = S_d\,\pi DL/12 \tag{49}$$

Rectangular
$$E_s = 2\,S_d\,(H + W)\,L/12 \tag{50}$$

where

S_d = unit ductwork cost/ft^2 (including material and labor)
H = duct height, in.
W = duct width, in.
L = duct length, ft

The cost of space required by ducts and equipment is another important factor of duct optimization. Including this cost reduces the size of ducts, thereby increasing energy consumption. Since the space available for ductwork is usually not used for anything else, its cost is ignored.

Both electrical energy rates and duct work costs vary widely. For example, electric energy costs vary by a factor of 9 to 1 between New York and Seattle (DOE 1984). Black iron rectangular ductwork can cost about 3.9 times that of spiral ductwork (Wendes 1989). Combining these ratios yields a factor of 34 to 1 based on locale and type of ductwork. Therefore, a great potential exists for

reducing duct system life-cycle cost due to energy and ductwork cost variations.

The following constraints are necessary for duct optimization (Tsal and Adler 1987):

- *Continuity.* For each node, the flow in equals the flow out.
- *Pressure balancing.* The total pressure loss in each path must equal the fan total pressure; or, in effect, at any junction, the total pressure loss for all paths is the same.
- *Nominal duct size.* Ducts are constructed in discrete, nominal sizes. Each diameter of a round duct or height and width of a rectangular duct is rounded to the nearest increment, usually 1 or 2 in. If a lower nominal size is selected, the initial cost decreases, but the pressure loss increases and may exceed the fan pressure. If the higher nominal size is selected, the opposite is true—the initial cost increases, but the section pressure loss decreases. However, this lower pressure at one section may allow smaller ducts to be selected for sections that follow. Therefore, optimization must consider size rounding.
- *Air velocity restriction.* The maximum allowable velocity is an acoustic limitation (ductwork regenerated noise).
- *Construction restriction.* Architectural limits may restrict duct sizes. If air velocity or construction constraints are violated during an iteration, a duct size must be calculated. The pressure loss calculated for this preselected duct size is considered a fixed loss.

Calculation procedure. The T-method comprises the following major procedures:

- *System condensing.* This procedure condenses a multiple-section duct system into a single imaginary duct section with identical hydraulic characteristics and the same owning cost as the entire system. By Tsal *et al.* [1988, Equation (1.41)], two or more converging or diverging sections and the common section at a junction can be replaced by one condensed section. By applying Tsal's equation from junction to junction in the direction to the root section (fan), the entire supply and return systems can be condensed into one section (a single resistance).
- *Fan selection.* From the condensed system, the ideal optimum fan total pressure P_t^{opt} is calculated and used to select a fan. If a fan with a different pressure is selected, its pressure (P^{opt}) is considered optimum.
- *System expansion.* The expansion process distributes the available fan pressure P^{opt} throughout the system. Unlike the condensing procedure, the expansion procedure starts at the root section and continues in the direction of the terminals.

Economic analysis. Tsal *et al.* (1988) describe the calculation procedure and include an economic analysis of the T-method.

T-Method, Simulation

T-method simulation, also developed by Tsal (1990), determines the flow in each duct section of an existing system with a known operating fan performance curve. The simulation version of T-method converges very efficiently. Usually three iterations are sufficient to obtain a solution with a high degree of accuracy.

Calculation procedure. The simulation version of T-method includes the following major procedures:

- *System condensing.* This procedure condenses a branched tee system into a single imaginary duct section with identical hydraulic characteristics. Two or more converging or diverging sections and the common section at a junction can be replaced by one condensed section [by Equation (18) in Tsal *et al.* (1990)]. By applying Tsal's equation from junction to junction in the direction to the root section (fan), the entire system, including supply and return subsystems, can be condensed into one imaginary section (a single resistance).
- *Fan operating point.* This step determines the system flow and pressure by locating the intersection of the fan performance and system curves, where the system curve is represented by the imaginary section from the previous step.
- *System expansion.* Knowing system flow and pressure, the previously condensed imaginary duct section is expanded into the original system with flow distributed in accordance to the ratio of pressure losses calculated in the system condensing step.

Simulation applications. The need for duct system simulation appears in many HVAC problems. In addition to the following concerns that can be clarified by simulation, T-method is an excellent design tool for simulating the flow distribution within a system with various modes of operation.

- Flow distribution in a variable air volume (VAV) system due to terminal box flow diversity
- Airflow redistribution due to HVAC system additions and/or modifications
- System airflow analysis for partially occupied buildings
- Necessity to replace fans and/or motors when retrofitting an air distribution system
- Multiple-fan system operating condition when one or more fans shut down
- Pressure differences between adjacent confined spaces within a nuclear facility when a design basis accident (DBA) occurs (Farajian *et al.* 1992)
- Smoke control system performance during a fire, when certain fire/smoke dampers close and others remain open

HVAC DUCT DESIGN PROCEDURES

The general procedure for HVAC system duct design is as follows:

1. Study the building plans and arrange the supply and return outlets to provide proper distribution of air within each space. Adjust calculated air quantities for duct heat gains or losses and duct leakage. Also, adjust the supply, return, and/or exhaust air quantities to meet space pressurization requirements.
2. Select outlet sizes from manufacturers' data (see Chaper 31).
3. Sketch the duct system, connecting supply outlets and return intakes with the air-handling units/air conditioners. Space allocated for supply and return ducts often dictates system layout and ductwork shape. Use round ducts whenever feasible.
4. Divide the system into sections and number each section. A duct system should be divided at all points where flow, size, or shape changes. Assign fittings to the section toward the supply and return (or exhaust) terminals. The following examples are for the fittings identified for Example 3 (Figure 12), and system section numbers assigned (Figure 13). For converging flow fitting 3, assign the straight-through flow to section 1 (toward terminal 1), and the branch to section 2 (toward terminal 4). For diverging flow fitting 24, assign the straight-through flow to section 13 (toward terminals 26 and 29) and the branch to section 10 (toward terminals 43 and 44). For transition fitting 11, assign the fitting to upstream section 4 [toward terminal 9 (intake louver)]. For fitting 20, assign the unequal area elbow to downstream section 9 (toward diffusers 43 and 44). The fan outlet diffuser, fitting 42, is assigned to section 19 (again, toward the supply duct terminals).
5. Size ducts by the selected design method. Calculate system total pressure loss; then select the fan (refer to Chapter 18 in the 1992 ASHRAE *Handbook—Systems and Equipment*).
6. Lay out the system in detail. If duct routing and fittings vary significantly from the original design, recalculate the pressure losses. Reselect the fan if necessary.
7. Resize duct sections to approximately balance pressures at each junction.

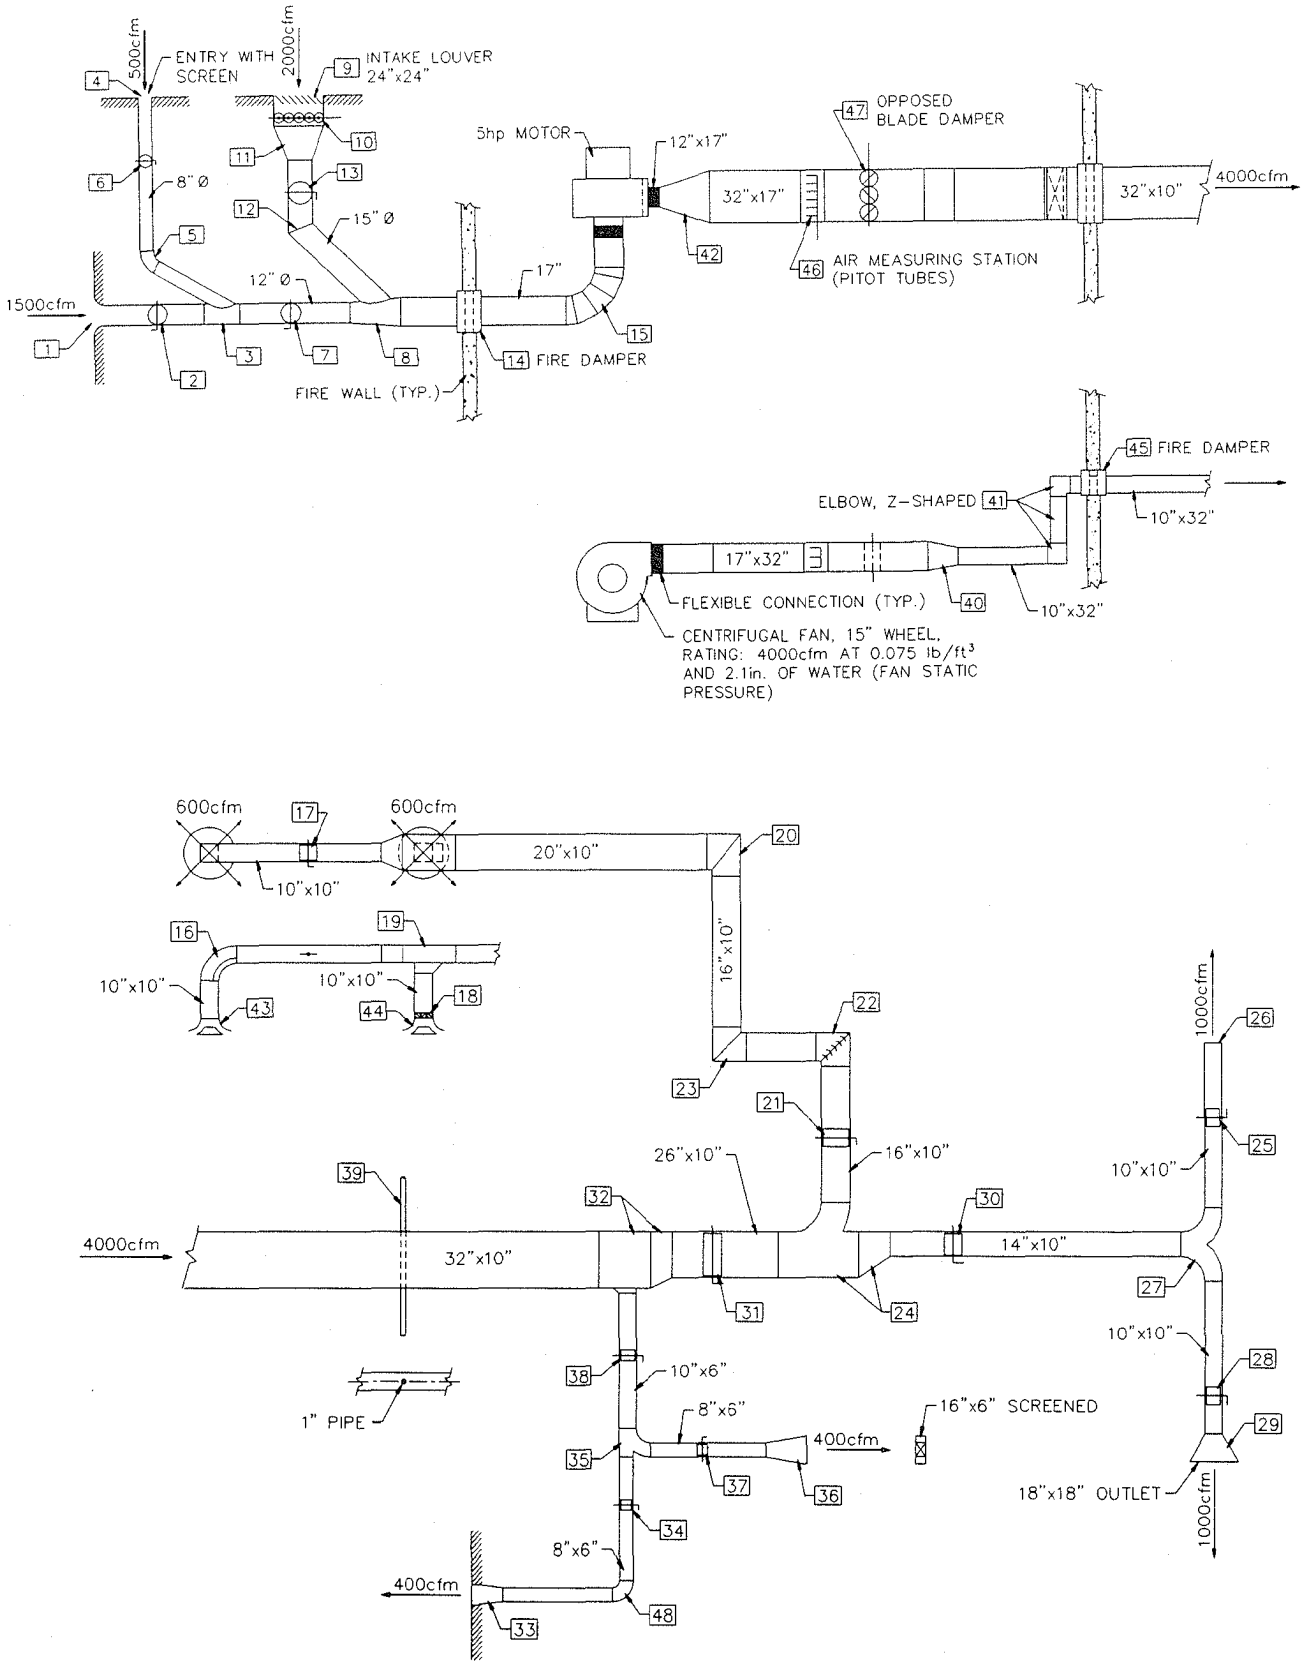

Fig. 12 Example 3 Schematic

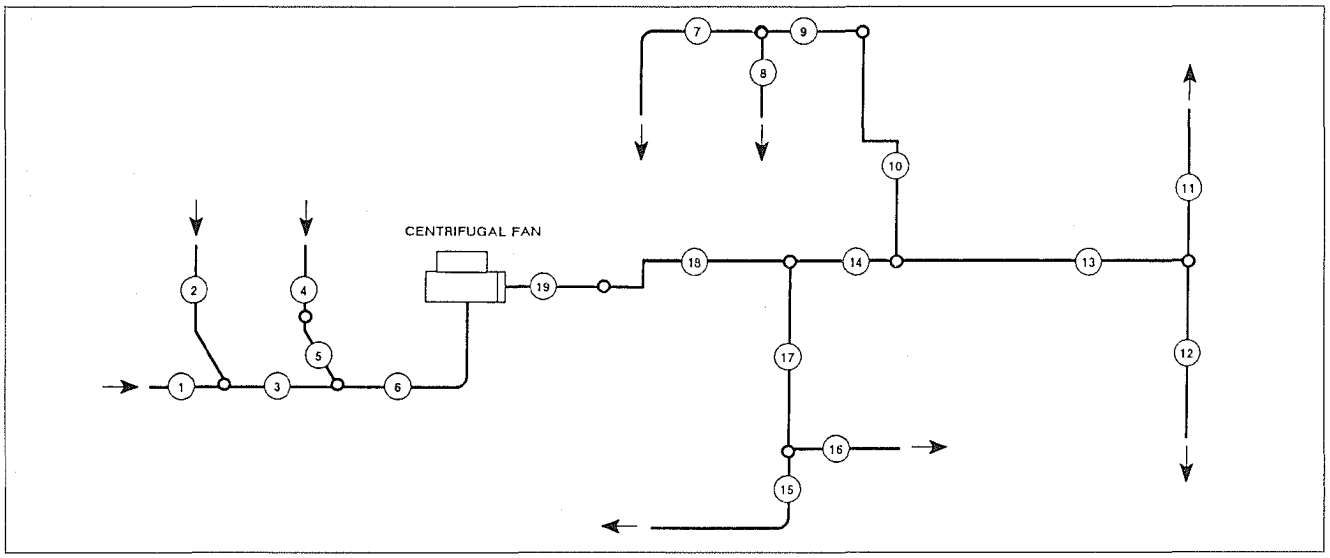

Fig. 13 Example 3—System Schematic with Section Numbers

8. Analyze the design for objectionable noise levels and specify sound attenuators as necessary. Refer to the section System and Duct Noise.

Example 3. For the system illustrated by Figure 12, size the ductwork by the equal friction method, and pressure balance the system by changing duct sizes (use 1-in. increments). Determine the system resistance and total pressure unbalance at the junctions. The airflow quantities are actual values adjusted for heat gains or losses, and ductwork is sealed (assume no leakage), galvanized steel ducts with transverse joints on 4-ft centers (ϵ = 0.0003 ft). Air is at standard conditions (0.075 lb_m/ft^3 density).

Since the primary purpose of Figure 12 is to illustrate calculation procedures, its duct layout is not typical of any real duct system. The layout includes fittings from the local loss coefficient tables, with emphasis on converging and diverging tees and various types of entries and discharges. The supply system is constructed of rectangular ductwork; the return system, round ductwork.

Solution: See Figure 13 for section numbers assigned to the system. The duct sections are sized within the suggested range of friction rate shown on the Friction Chart (Figure 5). Tables 9 and 10 give the total pressure loss calculations and the supporting summary of loss coefficients by sections. The straight duct friction factor and pressure loss were calculated by Equations (19) and (20). The fitting loss coefficients are from the ASHRAE Duct Fitting Database (1993). Loss coefficients were calculated automatically by the database program (not by manual interpolation). The pressure loss values in Table 9 for the diffusers (fittings 43 and 44), the louver (fitting 9), and the air-measuring station (fitting 46) are manufacturers' data.

The pressure unbalance at the junctions may be noted by referring to Figure 14, the total pressure grade line for the system. The system resistance P_t is 2.63 in. of water. Noise levels and the need for duct silencers were not evaluated. To calculate the fan static pressure, use Equation (18):

$$P_s = 2.63 - 0.50 = 2.1 \text{ in. of water}$$

where 0.50 in. of water is the fan outlet velocity pressure.

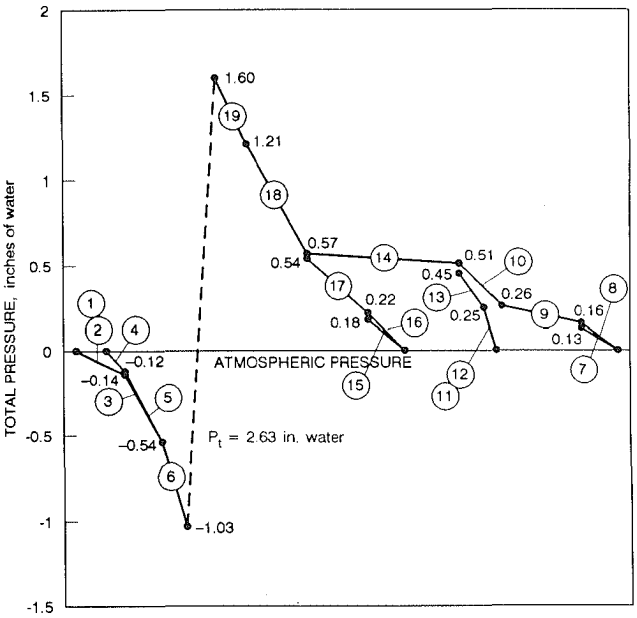

Fig. 14 Total Pressure Grade Line for Example 3

INDUSTRIAL EXHAUST SYSTEM DUCT DESIGN

Chapter 27 of the 1991 ASHRAE *Handbook—Applications* discusses design criteria, including hood design, for industrial exhaust systems. Exhaust systems conveying vapors, gases, and smoke can be designed by equal friction, static regain, or T-method. Systems conveying particulates are designed by the constant velocity method at duct velocities adequate to convey particles to the system air cleaner. For contaminant transport velocities, see Table 2, Chapter 27 of the 1991 ASHRAE *Handbook—Applications*.

Two pressure-balancing methods can be considered when designing industrial exhaust systems. One method uses balancing devices (*e.g.*, dampers, blast gates) to obtain design airflow through each hood. The other approach balances systems by adding resistance to ductwork sections, *i.e.*, changing duct size, selecting different fittings, and increasing airflow. This self-balancing method is preferred, especially for systems conveying abrasive materials. Where potentially explosive or radioactive materials are conveyed, the prebalanced system is mandatory, since contaminants could accumulate at the balancing devices. To balance systems by increasing airflow, use Equation (51), which assumes that all ductwork has the same diameter and that fitting loss coefficients, including main and branch tee coefficients, are constant.

[a]From Duct Fitting Database (ASHRAE 1993).
[b]Duct Fitting Database (ASHRAE 1993) data for this fitting reproduced in the Fitting Loss Coefficients section.

$$Q_c = Q_d (P_h/P_l)^{0.5} \quad (51)$$

where

Q_d = total airflow rate through low-resistance duct run, cfm
P_h = absolute value of pressure loss in high-resistance ductwork section(s), in. of water
P_l = absolute value of pressure loss in low-resistance ductwork section(s), in. of water
Q_c = airflow rate required to increase P_l to P_h, cfm

For systems conveying particulates, use elbows with a large centerline radius-to-diameter ratio (r/D) greater than 1.5 whenever possible. If the r/D is 1.5 or less, abrasion in dust-handling systems can reduce the life of elbows. Elbows are often made of seven or more gores, especially in large diameters. For converging flow fittings, a 30° entry angle is recommended to minimize energy losses and abrasion in dust-handling systems. For the entry loss coefficients of hoods and equipment for specific operations, refer to Chapter 27 of the 1991 ASHRAE *Handbook—Applications* and to ACGIH (1992).

Example 4. For the metalworking exhaust system in Figures 15 and 16, size the ductwork and calculate the fan static pressure requirement for an industrial exhaust designed to convey granular materials. Pressure balance the system by changing duct sizes and adjusting airflow rates. The minimum particulate transport velocity for the chipping and grinding table ducts (Sections 1 and 5, Figure 16) are 4000 fpm. For the ducts associated with the grinder wheels (Sections 2, 3, 4, and 5), the minimum duct velocity is 4500 fpm. Ductwork is galvanized steel, with the absolute roughness being 0.0003 ft. Assume standard air and that duct and fittings are available in the following sizes: 3-in. through 9.5 diameters in 0.5-in. increments, 10-in. through 37-in. diameters in 1-in. diameter increments, or 38-in. through 90-in. diameters in 2-in. diameter increments.

The building is one story, and the design wind velocity is 20 mph. For the stack, use Design J shown in Figure 15 of Chapter 14 for complete rain protection. The stack height, determined by calculations from Chapter 14, is 16 ft above the roof. This stack height is based on minimized stack downwash; therefore, the stack discharge velocity must exceed 1.5 times the design wind velocity.

Solution: For the contaminated ducts upstream of the collector, initial duct sizes and transport velocities are summarized below. The 4474-fpm velocity in Sections 2 and 3 are acceptable since the transport velocity is not significantly lower than 4500 fpm. For the next available duct size (4.5-in. diameter), the duct velocity is 5523 fpm, significantly greater than 4500 fpm.

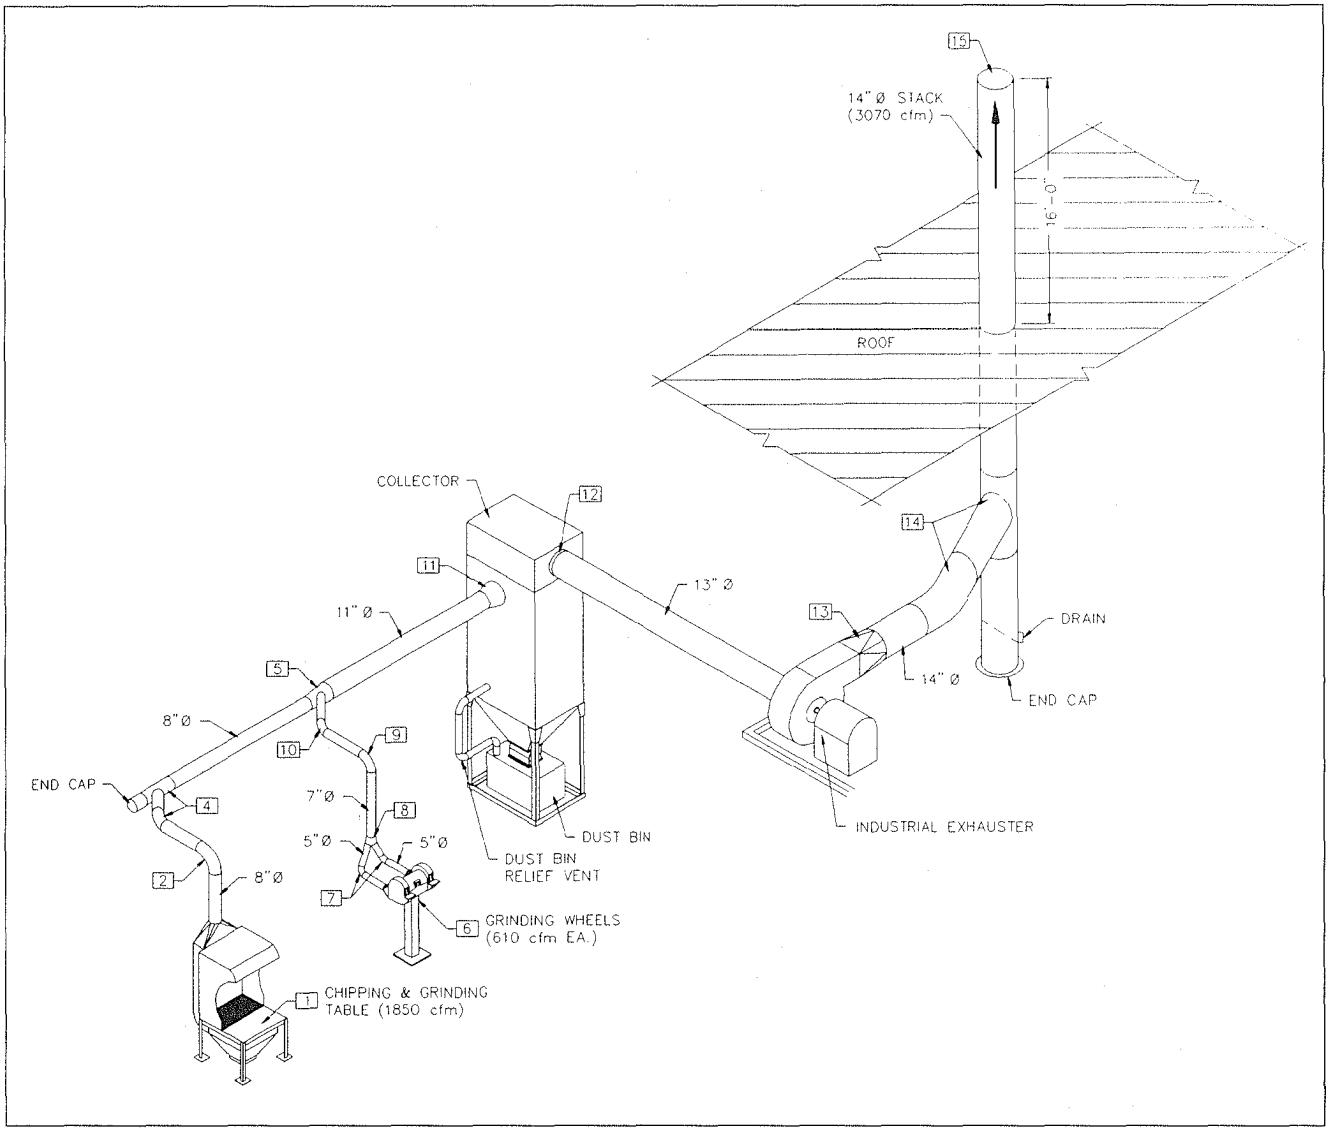

Fig. 15 Example 4—Metalworking Exhaust System

Duct Section	Design Airflow, cfm	Transport Velocity, fpm	Duct Diameter, in.	Duct Velocity, fpm
1	1800	4000	9	4074
2,3	610 each	4500	5	4474
4	1220	4500	7	4565
5	3020	4500	11	4576

The following tabulation summarizes design calculations up through the junction after Sections 1 and 4.

Design No.	D_1, in.	Δp_1, in. of water	Δp_{2+4}, in. of water	Imbalance, $\Delta p_1 - \Delta p_{2+4}$
1	9	1.46	3.09	−1.63
2	8.5	2.00	3.08	−1.08
3	8	2.79	3.00	−0.21
4	7.5	3.92	2.88	+1.04

Q_1 = 1800 cfm
Q_2 = 610 cfm; D_2 = 5 in. dia.
Q_3 = 610 cfm; D_3 = 5 in. dia.
Q_4 = 1220 cfm; D_4 = 7 in. dia.

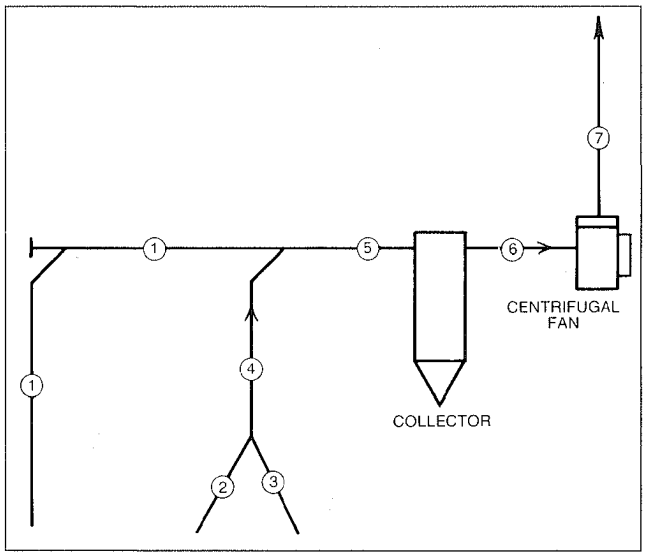

Fig. 16 Example 4—System Schematic with Section Numbers

For the intial design, Design 1, the imbalance between Section 1 and Section 2 (or 3) is 1.63 in. of water, with Section 1 requiring additional resistance. Decreasing Section 1 duct diameter by 0.5-in. increments results in the least imbalance, 0.21 in. of water, when the duct diameter is 8 in. (Design 3). Since Section 1 requires additional resistance, estimate the new airflow rate using Equation (51):

$$Q_{c,1} = (1800)\,(3.00/2.79)^{0.5} = 1870 \text{ cfm}$$

At 1870 cfm flow in Section 1, 0.13 in. of water imbalance remains at the junction of Sections 1 and 4. At 1850 cfm, balance is attained. The duct between the collector and the fan inlet is 13 in. round to match the fan inlet (12.75 in. diameter). To minimize downwash, the stack discharge velocity must exceed 2640 fpm, 1.5 times the design wind velocity (20 mph) as stated in the problem definition. Therefore, the stack is 14 in. round, and the stack discharge velocity is 2872 fpm.

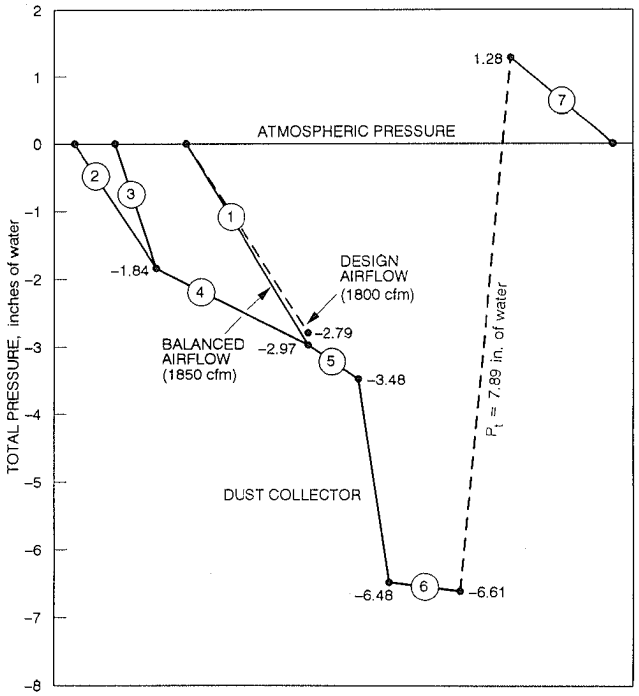

Fig. 17 Total Pressure Grade Line for Example 4

Table 11 Example 4—Total Pressure Loss Calculations by Sections

Duct Section[a]	Duct Element	Airflow, cfm	Duct Size	Velocity, fpm	Velocity Pressure, in. of water	Duct Length[b], ft	Summary of Fitting Loss Coefficients[c]	Duct Pressure Loss/100 ft, in. of water[d]	Total Pressure Loss, in. of water	Section Pressure Loss, in. of water

[a] See Figure 16.
[b] Length of ducts are to fitting centerlines.
[c] See Table 12.
[d] Duct pressure based on a 0.0003 ft absolute roughness factor.
[e] Collector manufacturers set the fabric bag cleaning mechanism to actuate at a pressure difference of 3.0 in. of water between the inlet and outlet plenums. The pressure difference across the clean media is approximately 1.5 in. of water.

Table 12 Example 4—Loss Coefficient Summary by Sections

Duct Section	Fitting Number	Type of Fitting	ASHRAE Fitting No.[a]	Parameters	Loss Coefficient
1	1	Hood[b]	—	Hood face area: 3 ft by 4 ft	0.25
	2	Elbow	CD3-10	90°, 7 gore, $r/D = 2.5$	0.11
	4	Capped wye (45°), with 45° elbow	ED5-7	$A_b/A_c = 1$	0.64 (C_b)
	5	Wye (30°), Main	ED5-1	$Q_s/Q_c = 0.60$, $A_s/A_c = 0.529$, $A_b/A_c = 0.405$	0.10 (C_s)
	Summation of Section 1 loss coefficients				1.10
2,3	6	Hood[c]	—	Type hood: For double wheels, Dia. = 22 in. each, Wheel width = 4 in. each, Type takeoff: Tapered	0.40
	7	Elbow	CD3-12	90°, 3 gore, $r/D = 1.5$	0.34
	8	Symmetrical wye (60°)	ED5-10	$Q_b/Q_c = 0.5$, $A_b/A_c = 0.510$	0.32 (C_b)
	Summation of Sections 2 and 3 loss coefficients				1.06
4	9	Elbow	CD3-10	90°, 7 gore, $r/D = 2.5$	0.11
	10	Elbow	CD3-13	60°, 3 gore, $r/D = 1.5$	0.19
	5	Wye (30°), Branch	ED5-1	$Q_b/Q_c = 0.40$, $A_s/A_c = 0.529$, $A_b/A_c = 0.405$	0.21 (C_b)
	Summation of Section 4 loss coefficients				0.51
5	11	Exit, conical diffuser to collector	ED2-1	$L = 24$ in., $L/D_o = 2.18$, $A_1/A_o \approx 16$	0.22
	Summation of Section 5 loss coefficients				0.22
6	12	Entry, Bellmouth from collector	ER2-1	$r/D_1 = 0.20$	0.00 (C_1)
	Summation of Section 6 loss coefficients				0.00
7	13	Diffuser, Fan outlet	SR7-17	Fan outlet size[d]: 10.125 in. by 12.125 in., $A_o/A_1 = 1.596$ (assume 14 in. by 14 in. outlet rather than 16 in. round), $L = 18$ in.	0.45 (C_o)
	14	Capped wye (45°), with 45° elbow	ED5-7	$A_b/A_c = 1$	0.64 (C_b)
	15	Stackhead	SD2-6	$D_e/D = 1$	1.0
	Summation of Section 7 loss coefficients				2.09

[a]From Duct Fitting Database (ASHRAE 1993).
[b]From *Industrial Ventilation* (ACGIH 1992, Figure VS-80-19).
[c]From *Industrial Ventilation* (ACGIH 1992, Figure VS-80-11).
[d]Fan specified: Industrial exhauster for granular materials: 21-in. wheel diameter, 12.75-in. inlet diameter, 10.125 in. by 12.125 in. outlet, 7.5-hp motor.

Table 11 summarizes the system losses by sections. The straight duct friction factor and pressure loss were calculated by Equations (19) and (20). Table 12 lists fitting loss coefficients and input parameters necessary to determine the loss coefficients. The fitting loss coefficients are from the ASHRAE Duct Fitting Database (1993). The fitting loss coefficient tables are included in the Fitting Coefficients section for illustration but can not be obtained exactly by manual interpolation since the coefficients were calculated by the duct fitting database algorithms (more significant figures). For a pressure grade line of the system, see Figure 17. The fan total pressure, calculated by Equation (16), is 7.89 in. of water. To calculate the fan static pressure, use Equation (18):

$$P_s = 7.89 - 0.81 = 7.1 \text{ in. of water}$$

where 0.81 in. of water is the fan outlet velocity pressure. The fan airflow rate is 3070 cfm and its outlet area is 0.853 ft^2 (10.125 in. by 12.125 in.). Therefore, the fan outlet velocity is 3600 fpm.

The hood suction for the chipping and grinding table hood is 2.2 in. of water, calculated by Equation (19) from Chapter 27 of the 1991 ASHRAE *Handbook—Applications* [$HS = (1 + 0.25)(1.74) = 2.2$ in. of water, where 0.25 is the hood entry loss coefficient C_o, and 1.74 is the duct velocity pressure P_v a few diameters downstream from the hood]. Similarly, the hood suction for each of the grinder wheels is 1.7 in. of water:

$$HS_{2,3} = (1 + 0.4)(1.24) = 1.7 \text{ in. of water}$$

where 0.4 is the hood entry loss coefficient, and 1.24 in. of water is the duct velocity pressure.

THIS chapter includes tables and charts to size piping for various fluid flow systems. Further details on specific piping systems can be found in appropriate chapters of the ASHRAE Handbook series.

PRESSURE DROP EQUATIONS

Pressure drop caused by fluid friction in fully developed flows of all "well behaved" (Newtonian) fluids is described by the Darcy-Weisbach equation

$$\Delta p = f\,(L/D)(\rho/g_c)(V^2/2) \tag{1}$$

where

Δp = pressure drop, lb_f/ft^2
f = friction factor, dimensionless (from Moody chart in Chapter 2)
L = length of pipe, ft
D = internal diameter of pipe, ft
ρ = fluid density at mean temperature, lb_m/ft^3
V = average velocity, ft/s
g_c = units conversion factor, $ft \cdot lb_m/lb_f \cdot s^2$

This equation is often presented in head or specific energy form as

$$\Delta h = (\Delta p/\rho)(g_c/g) = f(L/D)(V^2/2g) \tag{2}$$

where

Δh = head loss, ft
g = acceleration of gravity, ft/s^2

In this form, the density of the fluid does not appear explicitly (although it is in the Reynolds number, which influences f).

The friction factor f is a function of the pipe roughness ϵ, inside diameter D, and a dimensionless parameter, the Reynolds number

$$\mathrm{Re} = DV\rho/\mu \tag{3}$$

where

ϵ = absolute roughness of pipe wall, ft
μ = dynamic viscosity of fluid, $lb_m/ft \cdot s$

The friction factor is frequently presented on a Moody chart (Chapter 2), giving f as a function of Re with ϵ/D as a parameter.

A useful fit of smooth and rough pipe data for the usual turbulent flow regime is the Colebrook equation.

$$1/\sqrt{f} = 1.74 - 2\log\,[2\epsilon/D + 18.7/\mathrm{Re}\sqrt{f}\,]$$

Another form of this equation appears in Chapter 2, but the two are equivalent. The present form is more useful in showing behavior at limiting cases—as ϵ/D approaches 0 (smooth limit), the $18.7/\mathrm{Re}\sqrt{f}$ term dominates; at high ϵ/D and Re (fully rough limit), the $2\epsilon/D$ term dominates.

The equation is implicit in f; f appears on both sides, so a value for f is usually obtained iteratively.

A less widely used alternative to the Darcy-Weisbach formulation for calculating pressure drop is the Hazen-Williams equation, expressed as

$$\Delta p = 3.022\,L(V/C)^{1.852}\,(1/D^{1.167})(\rho g/g_c) \tag{4}$$

or

$$\Delta h = 3.022\,L(V/C)^{1.852}\,(1/D^{1.167}) \tag{5}$$

where C = roughness factor.

Typical values of C are 150 for plastic pipe and copper tubing, 140 for new steel pipe, down to 100 and below for badly corroded or very rough pipe.

Valve and Fitting Losses

Valves and fittings cause pressure losses greater than those caused by the pipe alone. One formulation expresses losses as

$$\Delta p = k(\rho/g_c)(V^2/2) \text{ or } \Delta h = k(V^2/2g) \tag{6}$$

where k = geometry and size dependent loss coefficient (Tables 1, 2, and 3).

Example 1. Determine the pressure drop for 60°F water flowing at 4 ft/s through a nominal 1-in., 90° screwed ell.

Solution: From Table 1, the k for a 1-in., 90° screwed ell is 1.5. $\Delta p = 1.5 \times 62.4/32.2 \times 4^2/2 = 23.3\ lb/ft^2$ or 0.16 psi.

The loss coefficient for valves appears in another form as C_v, a dimensional coefficient expressing the flow through a valve at a specified pressure drop.

$$Q = C_v\sqrt{\Delta p} \tag{7}$$

where C_v = volume flow, gal/min for a 1-psi pressure drop.

Example 2. Determine the volume flow through a valve with $C_v = 10$ for an allowable pressure drop of 5 psi.

Solution: $Q = 10\sqrt{5} = 22.4$ gpm.

Alternative formulations express fitting losses in terms of equivalent lengths of straight pipe (Tables 4 and 5, Figure 4). Pressure loss data for fittings are also presented in Idelchik (1986).

The preparation of this chapter is assigned to TC 6.1, Hydronic and Steam Equipment and Systems.

Calculating Pressure Losses

The most common engineering design flow loss calculation selects a pipe size for the desired total flow rate and available or allowable pressure drop.

Since either formulation of fitting losses requires a known diameter, pipe size must be selected before calculating the detailed influence of fittings. A frequently used rule of thumb assumes that the design length of pipe is 50 to 100% longer than actual to account for fitting losses. After a pipe diameter has been selected on this basis, the influence of each fitting can be evaluated.

WATER PIPING

FLOW RATE LIMITATIONS

Stewart and Dona (1987) surveyed the literature relating to water flow rate limitations. This section briefly reviews some of the findings. Noise, erosion, and installation and operating costs all limit the maximum and minimum velocities in piping systems. If piping sizes are too small, noise and erosion levels and pumping costs can be unfavorable; if piping sizes are too large, installation costs are excessive. Therefore, pipe sizes are chosen to minimize initial cost while avoiding the undesirable effects of high velocities.

A variety of upper limits of water velocity and/or pressure drop in piping and piping systems is used. One recommendation places a velocity limit of 4 ft/s for 2-in. pipe and smaller, and a pressure drop limit of 4 ft of water/100 ft for piping over 2 in. Others are based on the type of service (Table 6) or the annual operating hours (Table 7). These limitations are imposed either to control the levels of pipe and valve noise, erosion, and water hammer pressure or for economic reasons. Carrier (1960) recommends that the velocity not exceed 15 ft/s in any case.

Velocity-dependent noise in piping and piping systems results from any or all of four sources: turbulence, cavitation, release of entrained air, and water hammer. In investigations of flow-related noise, Marseille (1965), Ball and Webster (1976), and Rogers (1953, 1954, 1956) report that velocities on the order of 10 to 17 ft/s lie within the range of allowable noise levels for residential and commercial buildings. The experiments showed considerable variation in the noise levels obtained for a specified velocity. Generally, systems with longer length pipe and with more numerous fittings and valves were noisier. In addition, sound measurements were taken under widely differing conditions; for example, some tests used plastic-covered pipe, while others did not. Thus, no detailed correlations relating sound level to flow velocity in generalized systems are available.

The noise generated by fluid flow in a pipe system increases sharply if cavitation or the release of entrained air occurs. Usually

Table 6 Water Velocities Based on Type of Service

Type of Service	Velocity, ft/s	Reference
General service	4 to 10	a, b, c
City water	3 to 7	a, b
	2 to 5	c
Boiler feed	6 to 15	a, c
Pump suction and drain lines	4 to 7	a, b

the combination of a high water velocity with a change in flow direction or a decrease in the cross section of a pipe causing a sudden pressure drop is necessary to cause cavitation. Ball and Webster (1976) found that at their maximum velocity of 42 ft/s, cavitation in straight 3/8 and 1/2 in. pipe did not occur; using the apparatus with two elbows, cold water velocities up to 21 ft/s did not cause cavitation. Cavitation did occur in orifices of 1:8 area ratio (orifice flow area is 1/8 of pipe flow area) at 5 ft/s and at 10 ft/s for 1:4 area ratio orifices (Rogers 1954).

Some data are available for predicting hydrodynamic noise generated by control valves. The Instrument Society of America (1985) compiled prediction correlations in an effort to develop control valves for reduced noise levels. The correlation to predict hydrodynamic (liquid) noise from control valves is

$$SL = 10 \log C_v + 20 \log \Delta p - 30 \log t + 5 \qquad (8)$$

where

SL = sound level, dB
C_v = flow coefficient, $Q/(sg/\Delta p)^{0.5}$, gpm/(psi)$^{0.5}$
Q = flow rate, gpm
sg = specific gravity of liquid
Δp = pressure drop across valve, psi
t = downstream pipe wall thickness, in.

Air entrained in water usually has a higher partial pressure than the water. Even when flow rates are small enough to avoid cavitation, the release of entrained air may create noise. Every effort should be made to vent the piping system or otherwise remove entrained air.

Erosion

Erosion in piping systems is caused by water bubbles, sand, or other solid matter impinging on the inner surface of the pipe. Generally, at velocities lower than 100 ft/s, erosion is not significant as long as there is no cavitation. When solid matter is entrained in the fluid at high velocities, erosion occurs rapidly, especially in bends. Thus, high velocities should not be used in systems where sand or other solids are present or where slurries are transported.

Allowances for Aging

With age, the internal surfaces of pipes become increasingly rough, which reduces the available flow with a fixed pressure

supply. However, designing with excessive age allowances may result in oversized piping. Age-related decreases in capacity depend on the type of water, type of pipe material, temperature of water, and type of system (open or closed) and include:

- Sliming (biological growth or deposited soil on the pipe walls) occurs mainly in unchlorinated, raw water systems.
- Caking of calcareous salts occurs in hard water, *i.e.*, water bearing calcium salts, and increases with increases in the temperature of the water.
- Corrosion (incrustations of ferrous and ferric hydroxide on the pipe walls) occurs in metal pipe in soft water. Since oxygen is necessary for corrosion to take place, significantly more corrosion takes place in open systems.

Allowances for expected decreases in capacity are sometimes treated as a specific amount (percentage). Dawson and Bowman (1933) added an allowance of 15% friction loss to new pipe (equivalent to an 8% decrease in capacity). Hennington *et al.* (1981) increased the friction loss by 15 to 20% for closed piping systems and 75 to 90% for open systems. Carrier (1960) indicates a factor of approximately 1.75 between friction factors for closed and open systems.

Obrecht and Pourbaix (1967) differentiated between the corrosive potential of different metals in potable water systems and concluded that iron is the most severely attacked, then galvanized steel, lead, copper, and finally copper alloys (*i.e.*, brass). Hunter (1941) and Freeman (1941) showed the same trend. After four years of cold and hot water use, copper pipe had a capacity loss of 25 to 65%. Aged ferrous pipe has a capacity loss of 40 to 80%. Smith (1983) recommended increasing the design discharge by 1.55 for uncoated cast iron, 1.08 for iron and steel, and 1.06 for cement or concrete.

The Plastic Pipe Institute (1971) found that corrosion is not a problem in plastic pipe, the capacity of plastic pipe used in Europe and the United States remaining essentially the same after 30 years in use.

Extensive age-related flow data are available for use with the Hazen-Williams empirical equation. Difficulties arise in its application, however, because the original Hazen-Williams roughness coefficients are valid only for the specific pipe diameters, water velocities, and water viscosities used in the original experiments. Thus, when the *C*s are extended to different diameters, velocities, and/or water viscosities, errors of up to about 50% in pipe capacity can occur (Williams and Hazen 1933, Sanks 1978).

Water Hammer

When any moving fluid (not just water) is abruptly stopped, as when a valve closes suddenly, large pressures can develop. While detailed analysis requires knowledge of the elastic properties of the pipe and the flow-time history, the limiting case of rigid pipe and instantaneous closure is simple to calculate. Under these conditions

$$p_h = \rho c_s V / g_c \qquad (9)$$

where

p_h = pressure rise caused by water hammer, lb_f/ft^2
ρ = fluid density, lb_m/ft^3
c_s = velocity of sound in fluid, ft/s
V = fluid flow velocity, ft/s

The c_s for water is 4720 ft/s, although the elasticity of the pipe reduces the effective value.

Example 3. What is the maximum pressure rise if water flowing at 10 ft/s is stopped instantaneously?

Solution: $p_h = 62.4 \times 4720 \times 10/32.2 = 91468\ lb/ft^2$
$= 635$ psi

Other Considerations

Not discussed in detail in this chapter, but of potentially great importance, are a number of physical and chemical considerations: pipe and fitting design, materials, and joining methods must be appropriate for working pressures and temperatures encountered, as well as being suitably resistant to chemical attack by the fluid.

Other Piping Materials and Fluids

For fluids not included in this chapter or for piping materials of different dimensions, manufacturers' literature frequently supplies pressure drop charts. The Darcy-Weisbach equation and the Moody chart or the Colebrook equation can be used as an alternative to pressure drop charts or tables.

HOT AND CHILLED WATER PIPE SIZING

The Darcy-Weisbach equation with friction factors from the Moody chart or Colebrook equation (or, alternatively, the Hazen-Williams equation) is fundamental to calculating pressure drop in hot and chilled water piping; however, charts calculated from these equations (such as Figures 1, 2, and 3) provide easy determination of pressure drops for specific fluids and pipe standards. In addition, tables of pressure drops can be found in Hydraulic Institute (1979) and Crane Co. (1976).

Most tables and charts for water are calculated for properties at 60°F. Using these for hot water introduces some error, although the answers are conservative; *i.e.*, cold water calculations overstate the pressure drop for hot water. Using 60°F water charts for 200°F water should not result in errors in Δp exceeding 20%.

Range of Usage of Pressure Drop Charts

General design range. The general range of pipe friction loss used for design of hydronic systems is between 1 and 4 ft/100 ft. A value of 2.5 ft/100 ft represents the *mean* to which most systems are designed. Wider ranges may be used in specific designs, if certain precautions are taken.

Piping noise. Closed loop hydronic system piping is generally sized below certain arbitrary upper limits, such as a velocity limit of 4 ft/s for 2-in. pipe and under, and a pressure drop limit of 4 ft per 100 ft for piping over 2 in. in diameter. Velocities in excess of 4 ft/s can be used in piping of larger size. This limitation is generally accepted, although it is based on relatively inconclusive experience with noise in piping. Water *velocity noise* is not caused by water but by free air, sharp pressure drops, turbulence, or a combination of these, which in turn cause cavitation or flashing of water into steam. Therefore, higher velocities may be used if proper precautions are taken to eliminate air and turbulence.

Air Separation

Because piping noise can be caused by free air, the hydronic system must be equipped with air separation devices to minimize the amount of entrained air in the piping circuit. Air should be vented at the highest point of the system.

In the absence of such venting, air can be entrained in the water and carried to separation units at flow velocities of 1.5 to 2 ft/s or more in pipe sizes of 2 in. and under. Minimum velocities of 2 ft/s are therefore recommended. For pipe sizes 2 in. and over, minimum velocities corresponding to a head loss of 0.75 ft/100 ft are normally used. Maintenance of minimum velocities is particularly important in the upper floors of high-rise buildings when the air tends to come out of solution because of reduced pressures. Higher velocities should be used in *down-comer* return mains feeding into air separation units located in the basement.

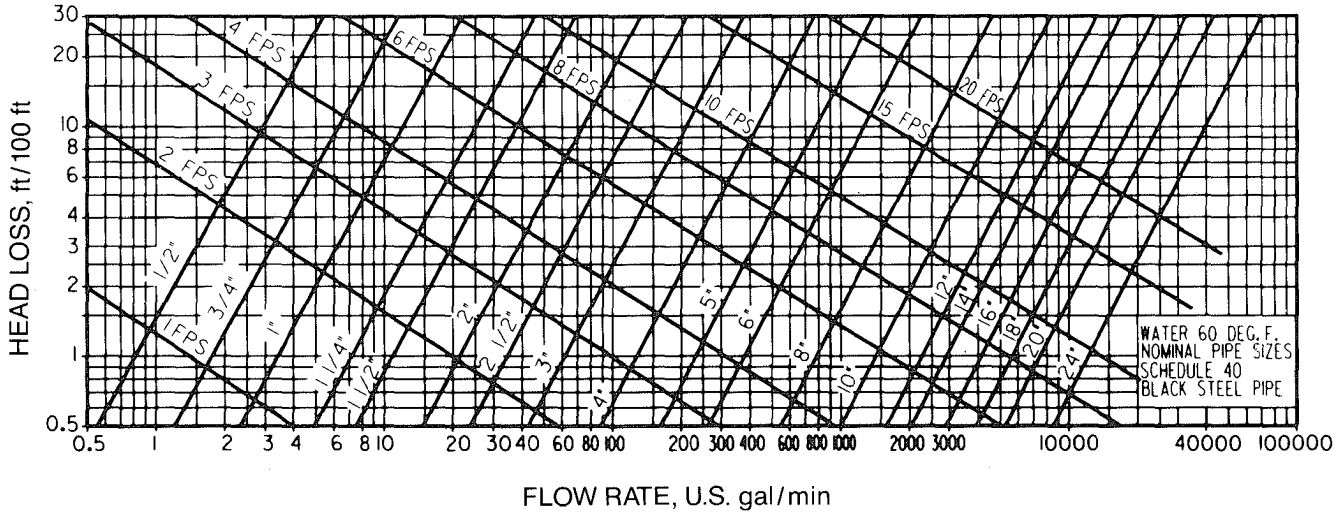

Fig. 1 Friction Loss for Water in Commercial Steel Pipe (Schedule 40)

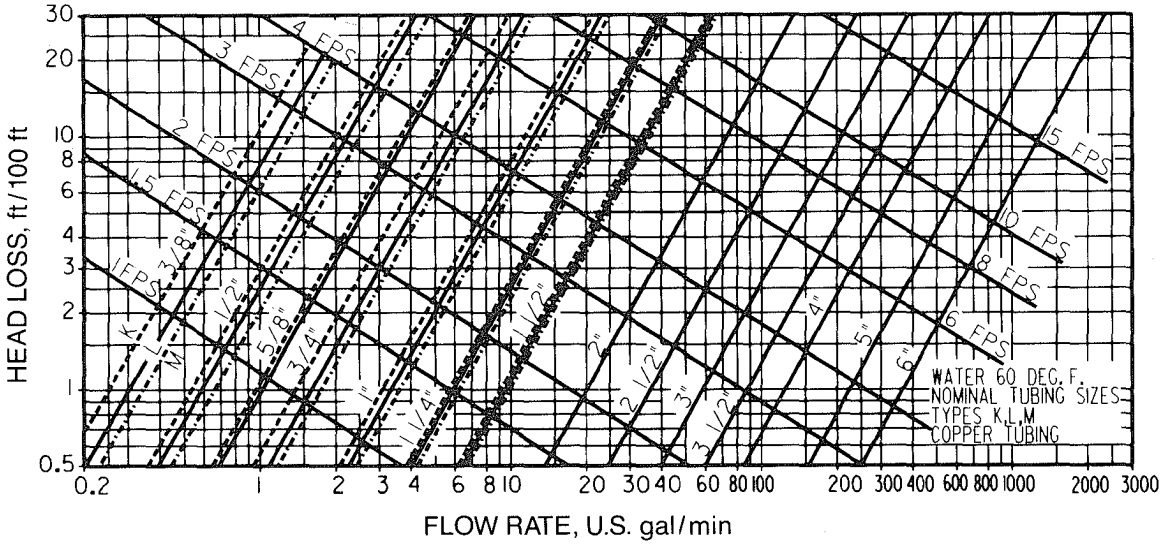

Fig. 2 Friction Loss for Water in Copper Tubing (Types K, L, M)

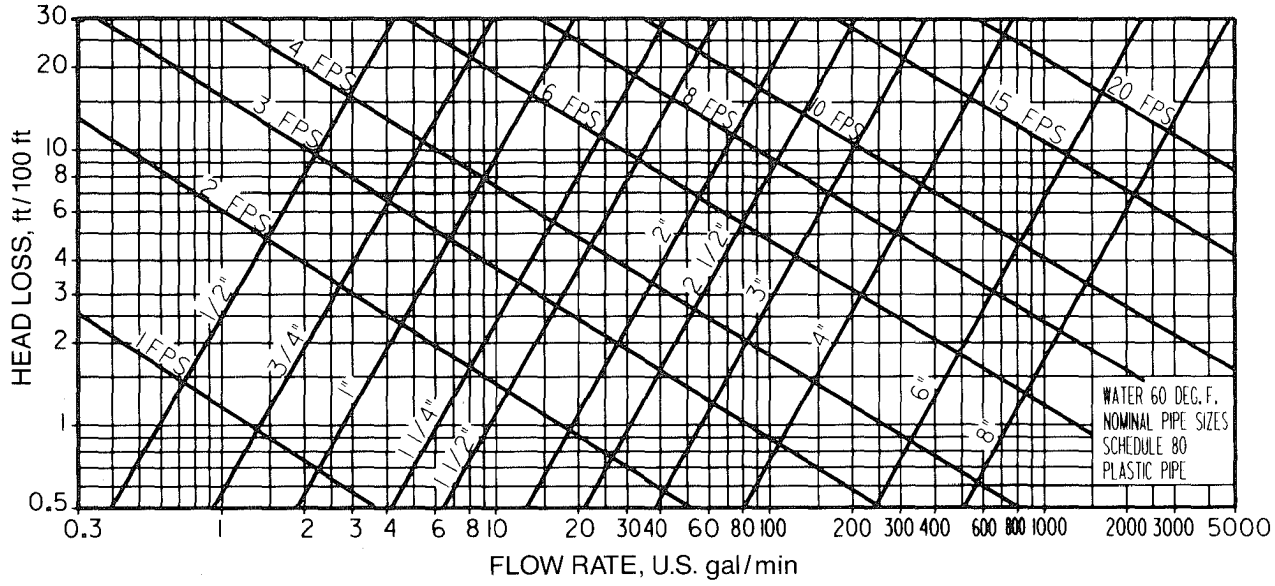

Fig. 3 Friction Loss for Water in Plastic Pipe (Schedule 80)

Example 4. Determine pipe size for circuit requiring 20 gpm flow.

Solution: Enter Figure 1 at 20 gpm, read up to pipe size within normal design range, select 1-1/2 in. Velocity is 3.1 ft/s, which is between 2 and 4. Pressure loss is 2.9 ft/100 ft, which is between 1 and 4 ft/100 ft.

Valve and Fitting Pressure Drop

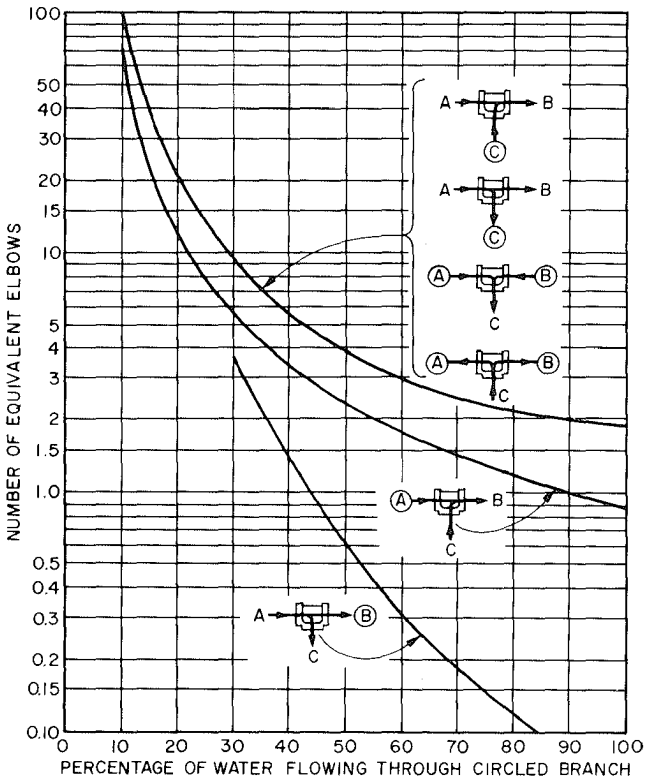
Valve and fitting pressure drop can be listed in elbow equivalents, with an elbow being equivalent to a length of straight pipe. Table 4 lists equivalent lengths of 90° elbows; Table 5 lists elbow equivalents for valves and fittings for iron and copper.

Example 5. Determine equivalent feet of pipe for a 4-in. open gate valve at a flow velocity of approximately 4 ft/s.

Solution: From Table 4, at 4 ft/s, each equivalent elbow is equal to 10.6 ft of 4-in. pipe. From Table 5, the 4-in. gate valve is equal to 0.5 elbows. The actual equivalent pipe length (added to measure circuit length for pressure drop determination) will be 10.6 × 0.5, or 5.3 equivalent feet of 4-in. pipe.

Tee fitting pressure drop. Pressure drop through pipe tees varies with flow through the branch. Figure 4 illustrates pressure drops for nominal 1-in. tees of equal inlet and outlet sizes and for the flow patterns illustrated. Idelchik (1986) also presents data for threaded tees.

Different investigators present tee loss data in different forms, and it is sometimes difficult to reconcile results from several sources. As an estimate of the upper limit to tee losses, a pressure or head loss coefficient of 1.0 may be assumed for entering and leaving flows (*i.e.*, $\Delta p = 1.0\,\rho V_{in}^2/2 + 1.0\,\rho V_{out}^2/2$).



Notes: 1. The chart is based on straight tees, *i.e.*, branches A, B, and C are the same size.
2. Pressure loss in desired circuit is obtained by selecting proper curve according to illustrations, determining the flow at the circled branch, and multiplying the pressure loss for the same size elbow at the flow rate in the circled branch by the equivalent elbows indicated.
3. When the size of an outlet is reduced, the equivalent elbows shown in the chart do not apply. Therefore, the maximum loss for any circuit for any flow will not exceed 2 elbow equivalents at the maximum flow (gpm) occurring in any branch of the tee.
4. The top curve of chart is average of 4 curves, one for each circuit shown.

Fig. 4 Elbow Equivalents of Tees at Various Flow Conditions
(Giesecke and Badgett 1931, 1932)

Example 6. Determine the pressure or head losses for a 1-in. (all openings) threaded pipe tee flowing 25% to the side branch, 75% through. The entering flow is 10 gpm (3.71 ft/s).

Solution: From Figure 4, bottom curve, the number of equivalent elbows for the through-flow is 0.15 elbows; the through-flow is 7.5 gpm (2.78 ft/s); and the pressure loss is based on the exit flow rate. Table 4 gives the equivalent length of a 1-in. elbow at 3 ft/s as 2.7 ft. Using Equations (1) and (2) (friction factor f = 0.0290, diameter = 0.0874 ft):

$$\Delta p = (0.15)(0.0290)(2.7/0.0874)(62.4)(2.78^2)/[(2)(32.2)]$$

Δp = 1.01 lb/ft^2 = 0.00699 lb/in^2 for pressure drop, or

$$\Delta h = (0.15)(0.0290)(2.7/0.0874)(2.78^2)/[(2)(32.2)]$$

Δh = 0.0161 ft for head loss

From Figure 4, top curve, the number of equivalent elbows for the branch flow of 25% is 13 elbows; the branch flow is 2.5 gpm (0.93 ft/s); and the pressure loss is based on the exit flow rate. Table 4 gives the equivalent of a 1-in. elbow at 1 ft/s as 2.2 ft. Using Equations (1) and (2) (friction factor f = 0.0350, diameter = 0.0874 ft):

$$\Delta p = (13)(0.0350)(2.2/0.0874)(62.4)(0.93^2)/[(2)(32.2)]$$

Δp = 9.60 lb/ft^2 = 0.0667 lb/in^2 for pressure drop, or

$$\Delta h = (13)(0.0350)(2.2/0.0874)(0.93^2)/[(2)(32.2)]$$

Δh = 0.154 ft for head loss

HOT AND COLD SERVICE WATER PIPING

Before any part of a water piping system can be sized, the probable rate of flow in any particular section of piping should be determined. The rate of flow in the service line, risers, and main branches, however, is rarely equal to the sum of the rates of flow of all connected fixtures. In fact, the probability that every fixture in a large group will be in use at the same time is so remote that designing the piping to take care of such simultaneous flow is unnecessarily expensive.

The demand load in building water supply systems cannot be determined exactly and is not readily standardized. The two main problems to be considered are (1) the satisfactory supply of water for a given fixture and (2) the number of fixtures that are assumed to be in use at the same time.

The minimum satisfactory flow depends largely on the living standard and professional needs of the consumer, family size, garden requirements, and similar factors. Depending on these factors, the per capita water consumption for domestic use usually varies between 20 and 80 gal per day. Type of dwelling also has considerable influence on water consumption.

Conclusive water consumption data for housing projects in the United States have not been gathered. The daily per capita water consumption in housing projects apparently falls between the consumption in apartment houses and single dwellings at the same geographical location. A daily per capita water consumption of 70 gal can be used as a safe design figure for housing projects, as is indicated by New York City housing project records.

Table 8 gives the rate of flow desirable for many common fixtures and the average pressure necessary to give this rate of flow. The pressure varies with fixture design. Generally, the lower the quality of the faucet, the greater the pressure required.

In estimating the load, the rate of flow is frequently computed in *fixture units*, which are relative indicators of flow. Table 9 gives the demand weights in terms of fixture units for different plumbing fixtures under several conditions of service, and Figure 5 gives

the estimated demand in gallons per minute corresponding to any total number of *fixture units*. Figures 6 and 7 provide more accurate estimates at the lower end of the scale.

The estimated demand load for fixtures used intermittently on any supply pipe can be obtained by multiplying the number of each kind of fixture supplied through that pipe by its weight from Table 9, adding the products, and then referring to the appropriate curve of Figures 5, 6, or 7 to find the demand corresponding to the total fixture units. In using this method, note that the demand for fixture or supply outlets other than those listed in the table of fixture units is not yet included in the estimate. The de-

Table 8 Proper Flow and Pressure Required during Flow for Different Fixtures

Fixture	Flow Pressure[a]	Flow, gpm
Ordinary basin faucet	8	3.0

Fig. 6 Estimate Curves for Demand Load
(Hunter 1941)

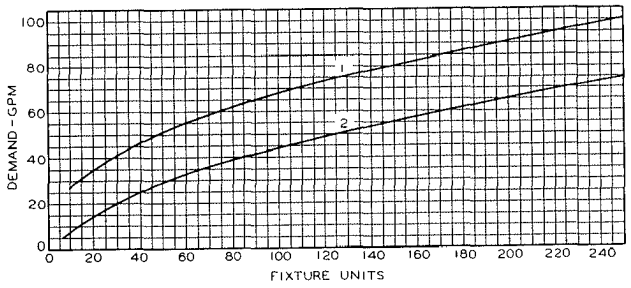

Fig. 7 Section of Figure 6 on Enlarged Scale

mands for outlets (such as hose connections and air-conditioning apparatus) that are likely to impose continuous demand during heavy use of the weighted fixtures, should be estimated separately and added to demand for fixtures used intermittently to estimate total demand.

The Hunter curves in Figures 5, 6, and 7 are based on use patterns in residential buildings and can be erroneous for other usages such as sports arenas. Williams (1976) discusses the Hunter assumptions and presents an analysis using alternative assumptions.

So far, the information presented shows the *design rate of flow* to be determined in any particular section of piping. The next step is to determine the *size* of piping. As water flows through a pipe, the pressure continually decreases along the pipe due to loss of energy from friction. The problem is then to ascertain the minimum pressure in the street main and the minimum pressure required to operate the topmost fixture. (A pressure of 15 psig may be ample for most flush valves, but reference should be made to the manufacturers' requirements. Some fixtures require a pressure up to 25 psig. A minimum of 8 psig should be allowed for other fixtures.) The pressure differential overcomes pressure losses in the distributing system and the difference in elevation between the water main and the highest fixture.

The pressure loss, in psi, resulting from the difference in elevation between the street main and the highest fixture, can be obtained by multiplying the difference in elevation in feet by the conversion factor 0.434.

Pressure losses in the distributing system consist of pressure losses in the piping itself, plus the pressure losses in the pipe fittings, valves, and the water meter, if any. Approximate design pressure losses and flow limits for disk-type meters for various rates of flow are given in Figure 8. Water authorities in many localities require compound meters for greater accuracy with varying flow; consult the local utility. Design data for compound meters differ from the data in Figure 8. Manufacturers give data on exact pressure losses and capacities.

Figure 9 shows the variation of pressure loss with rate of flow for various faucets and cocks. The water demand for hose bibbs or other large-demand fixtures taken off the building main frequently results in inadequate water supply to the upper floor of a building. This condition can be prevented by sizing the distribution system so that the pressure drops from the street main to all fixtures are the same. An ample building main (not less than 1 in. where possible) should be maintained until all branches to hose bibbs have been connected. Where the street main pressure is excessive and a pressure-reducing valve is used to prevent water hammer or excessive pressure at the fixtures, the hose bibbs should be connected ahead of the reducing valve.

The principles involved in sizing upfeed and downfeed systems are the same. In the downfeed system, however, the difference in elevation between the overhead supply mains and the fixtures provides the pressure required to overcome pipe friction. Since friction pressure loss and height pressure loss are not additive, as in an upfeed system, smaller pipes may be used with a downfeed system.

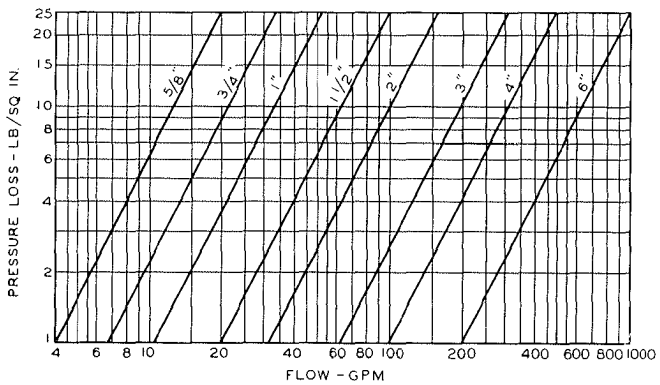

Fig. 8 Pressure Losses in Disk-Type Water Meters

Plastic Pipe

The maximum safe water velocity in a thermoplastic piping system (5 ft/s) depends on the specific details of the system and on the operating conditions. Higher velocities can be used in cases where the operating characteristics of valves and pumps are known so that sudden changes in flow velocity can be controlled. The total pressure in the system at any time (operating plus surge of water hammer) should not exceed 150% of the pressure rating of the system.

Procedure for Sizing Cold Water Systems

The recommended procedure for sizing piping systems is outlined below.

1. Sketch the main lines, risers, and branches, and indicate the fixtures to be served. Indicate the rate of flow of each fixture.
2. Using Table 9, compute the demand weights of the fixtures in fixture units.
3. Determine the total demand in fixture units and, using Figures 5, 6, or 7, find the expected demand in gal/min.
4. Determine the equivalent length of pipe in the main lines, risers, and branches. Since the sizes of the pipes are not known, the exact equivalent length of various fittings cannot be made. Add the equivalent lengths, starting at the street main and proceeding along the service line, the main line of the building, and up the riser to the top fixture of the up served.
5. Determine the average minimum pressure in the street main and the minimum pressure required for the operation of the topmost fixture. This should be 8 to 25 psi.

Fig. 9 Variation of Pressure Loss with Rate of Flow for Various Faucets and Cocks

6. Using Equation (1), calculate the approximate design value of the average pressure drop per 100 ft of pipe in equivalent length determined in paragraph 4.

$$\Delta p = (p_s - 0.434\,H - p_f - p_m)\,100/L \qquad (10)$$

where

Δp = average pressure loss per 100 ft of equivalent length of pipe, psi
p_s = pressure in street main, psig
p_f = minimum pressure required to operate topmost fixture, psig
p_m = pressure drop through water meter, psi
H = height of highest fixture above street main, ft
L = equivalent length determined in paragraph 4, ft

If the system is downfeed supply from a gravity tank, height of water in the tank, converted to psi by multiplying by 0.434, replaces the street main pressure, and the term 0.434 H is added instead of subtracted in calculating p. In this case, H is the vertical distance of the fixture below the bottom of the tank.

7. From the expected rate of flow, as determined in paragraph 3, and the value of p, calculated in paragraph 6, choose the sizes of pipe from Figures 1, 2, or 3.

Example 7. Assume a minimum street main pressure of 55 psig; a height of topmost fixture (a urinal with flush valve) above street main of 50 ft; a developed pipe length from water main to highest fixture of 100 ft; a total load on the system of 50 fixture units; and that the water closets are flush valve operated. Find the required size of supply main.

Solution: From Figure 7 the estimated peak demand is 51 gpm. From Table 8, the minimum pressure required to operate the topmost fixture is 15 psig. For a trial computation, choose the 1-1/2-in. meter. From Figure 8, the pressure drop through a 1-1/2-in. disk-type meter for a flow of 51 gpm is 6.5 psi.

The pressure drop available for overcoming friction in pipes and fittings is $55 - (0.434 \times 50 + 15 + 6.5) = 12$ psi.

At this point, estimate the equivalent pipe length of the fittings on the direct line from the street main to the highest fixture. The exact equivalent length of the various fittings cannot be determined since the pipe sizes of the building main, riser, and branch leading to the highest fixture are not yet known, but a first approximation is necessary to tentatively select pipe sizes. If the computed pipe sizes differ from those used in determining the equivalent length of pipe fittings, a recalculation will be necessary, using the computed pipe sizes for the fittings. For this example, assume that the total equivalent length of the pipe fittings is 50 ft.

The permissible pressure loss per 100 ft of equivalent pipe is $12 \times 100/(100 + 50) = 8$ psi. A 2-in. building main is adequate.

The sizing of the *branches* of the building main, the *risers*, and *fixture branches* follows these principles. For example, assume that one of the branches of the building main carries the cold water supply for 3 water closets, 2 bathtubs, and 3 lavatories. Using the permissible pressure loss of 8 psi per 100 ft, the size of branch (determined from Table 9 and Figures 1 and 7) is found to be 1-1/2 in. Items included in the computation of pipe size are given as follows:

Fixtures No. and Type	Fixture Units (Table 7 and Note C)	Demand (Figure 7)	Pipe Size (Figure 1)
3 flush valves	$3 \times 6 = 18$		
2 bath tubs	$0.75 \times 2 \times 2 = 3$		
3 lavatories	$0.75 \times 3 \times 1 = 2.25$		
Total	$= 23.25$	38 gpm	1-1/2 in.

Table 10 is a guide to minimum pipe sizing where flush valves are used.

Velocities exceeding 10 ft/s cause undesirable noise in the piping system. This usually governs the size of larger pipes in the system while, in small pipe sizes, the friction loss usually governs the selection because the velocity is low compared with friction loss. Velocity is the governing factor in downfeed systems, where friction loss is usually neglected. Velocity in branches leading to pump suctions should not exceed 5 ft/s.

Table 10 Allowable Number of 1-in. Flush Valves Served by Various Sizes of Water Pipe[a]

Pipe Size, in.	No. 1-in. Flush Valves
1-1/4	1
1-1/2	2-4
2	5-12
2-1/2	13-25
3	26-40
4	41-100

[a]Two 3/4-in. flush valves are assumed equal to one 1-in. flush valve, but can be served by a 1-in. pipe. Water pipe sizing must consider demand factor, available pressure, and length of run.

If the street pressure is too low to adequately supply upper-floor fixtures, the pressure must be increased. Constant or variable speed booster pumps, alone or in conjunction with gravity supply tanks, or hydropneumatic systems may be used.

Flow control valves for individual fixtures under varying pressure conditions automatically adjust the flow at the fixture to a predetermined quantity. These valves allow the designer to (1) limit the flow at the individual outlet to the minimum suitable for the purpose, (2) hold the total demand for the system more closely to the required minimum, and (3) design the piping system as accurately as is practicable for the requirements.

STEAM PIPING

Pressure losses in steam piping for flows of dry or nearly dry steam are governed by the equations in the Pressure Drop Equations section. This section incorporates these principles with other information specific to steam systems.

Pipe Sizes

Determining pipe sizes for a given load in steam heating depends on the following factors: (1) the initial pressure and the total pressure drop that can be allowed between the source of supply and at the end of the return system; (2) the maximum velocity of steam allowable for quiet and dependable operation of the system, taking into consideration the direction of condensate flow; and (3) the equivalent length of the run from the boiler or source of steam supply to the farthest heating unit.

Initial Pressure and Pressure Drop

Table 11 lists pressure drops commonly used with corresponding initial steam pressures for sizing steam piping.

Several factors, such as initial pressure and pressure required at the end of the line, should be considered, but it is most important that (1) the total pressure drop does not exceed the initial gage pressure of the system, and in practice it should never exceed one-

Table 11 Pressure Drops Used for Sizing Steam Pipe[a]

Initial Steam Pressure, psig	Pressure Drop per 100 ft	Total Pressure Drop in Steam Supply Piping
Vacuum return	2 to 4 oz/in^2	1 to 2 psi
0	0.5 oz/in^2	1 oz/in^2
1	2 oz/in^2	1 to 4 oz/in^2
2	2 oz/in^2	8 oz/in^2
5	4 oz/in^2	1.5 psi
10	8 oz/in^2	3 psi
15	1 psi	4 psi
30	2 psi	5 to 10 psi
50	2 to 5 psi	10 to 15 psi
100	2 to 5 psi	15 to 25 psi
150	2 to 10 psi	25 to 30 psi

[a]Equipment, control valves, and so forth must be selected based on delivered pressures.

half of the initial gage pressure; (2) the pressure drop is not great enough to cause excessive velocities; (3) a constant initial pressure should be maintained, except on systems specially designed for varying initial pressures, such as subatmospheric pressure, which normally operate under controlled partial vacuums; and (4) the rise in water from pressure drop does not exceed the difference in level, for gravity return systems, between the lowest point on the steam main, the heating units or the dry return, and the boiler water line.

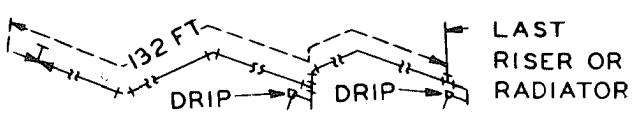
Maximum Velocity

For quiet operation, steam velocity should be 8000 to 12,000 fpm, with a maximum of 15,000 fpm. The lower the velocity, the quieter the system. When the condensate must flow against the steam, even in limited quantity, the velocity of the steam must not exceed limits above which (1) the disturbance between the steam and the counterflowing water may produce objectionable sound, such as water hammer, or (2) result in the retention of water in certain parts of the system until the steam flow is reduced sufficiently to permit the water to pass. The velocity at which these disturbances take place is a function of (1) pipe size, whether the pipe runs horizontally or vertically; (2) pitch of the pipe if it runs horizontally; (3) the quantity of condensate flowing against the steam; and (4) freedom of the piping from water pockets that, under certain conditions, act as a restriction in pipe size. Table 12 lists maximum capacities for various size steam lines.

Equivalent Length of Run

All tables for the flow of steam in pipes, based on pressure drop, must allow for pipe friction, as well as for the resistance of fittings and valves. These resistances are generally stated in terms of straight pipe; *i.e.*, a certain fitting produces a drop in pressure equivalent to the stated number of feet of straight run of the same size of pipe. Table 13 gives the number of feet of straight pipe usually allowed for the more common types of fittings and valves. In all pipe-sizing tables in this chapter, the *length of run* refers to the *equivalent length of run* as distinguished from the *actual length* of pipe. A common sizing method is to assume the length of run and to check this assumption after pipes are sized. For this purpose, the length of run is usually assumed to be double the actual length of pipe.

Example 8. Determine the length in feet of pipe to be added to actual length of run illustrated.



Measured length	=	132.0 ft
4-in. gate valve	=	1.9 ft
4 to 4 in. elbows	=	36.0 ft
2 to 4 in. tees	=	36.0 ft
Equivalent	=	205.9 ft

LOW-PRESSURE STEAM PIPING

Figure 10 is the basic chart for determining the flow rate and velocity of steam in Schedule 40 pipe for various values of pressure drop per 100 ft, based on zero psig saturated steam. Using the multiplier charts, Figure 10 can be used at all saturation pressures between 0 and 200 psig (see Example 10).

Values in Table 14 (taken from the basic chart) provide a more rapid means of selecting pipe sizes for the various pressure drops listed and for systems operated at 3.5 and 12 psig. The flow rates shown for 3.5 psig can be used for saturated pressures from 1 to 6 psig, and those shown for 12 psig can be used for saturated pressures from 8 to 16 psig with an error not exceeding 8%.

Both Figure 10 and Table 14 can be used where the flow of condensate does not inhibit the flow of steam. Columns *B* and *C* of Table 15 are used in cases where steam and condensate flow in opposite directions as in risers or runouts that are not dripped. Columns *D*, *E*, and *F* are for one-pipe systems and include risers, radiator valves and vertical connections, and radiator and riser runout sizes, all of which are based on the critical velocities of the steam to permit the counterflow of condensate without noise.

Return piping can be sized using Table 16, where pipe capacities for wet, dry, and vacuum return lines are shown for several values of pressure drop per 100 ft of equivalent length.

Table 13 Equivalent Length of Fittings to Be Added to Pipe Run

Nominal Pipe Diameter, in.	Length to Be Added to Run, ft Standard Elbow	Side Outlet Tee[b]	Gate Valve[a]	Globe Valve[a]	Angle Valve[a]

12	11,400	13,700	16,500	19,500	23,400	28,400	33,000	40,000	41,000	49,500	48,000	57,500	67,800	81,000

Notes:
1. Flow rate is in lb/h at initial saturation pressures of 3.5 and 12 psig. Flow is based on Moody friction factor, where the flow of condensate does not inhibit the flow of steam.
2. The flow rates at 3.5 psig cover saturated pressure from 1 to 6 psig, and the rates at 12 psig cover saturated pressure from 8 to 16 psig with an error not exceeding 8%.
3. The steam velocities corresponding to the flow rates given in this table can be found from the basic chart and velocity multiplier chart, Figure 11.

Table 15 Steam Pipe Capacities for Low-Pressure Systems

12	11,500	9500	—	—	—
16	22,000	19,000	—	—	—

Notes:
1. For one- or two-pipe systems in which condensate flows against the steam flow.
2. Steam at an average pressure of 1 psig is used as a basis of calculating capacities.

[a] Do not use Column *B* for pressure drops of less than 1/16 psi per 100 ft of equivalent run. Use Figure 10 or Table 13 instead.
[b] Pitch of horizontal runouts to risers and radiators should be not less than 0.5 in/ft. Where this pitch cannot be obtained, runouts over 8 ft in length should be one pipe size larger than that called for in this table.
[c] Do not use Column *D* for pressure drops of less than 1/24 psi per 100 ft of equivalent run, except on sizes 3 in. and over. Use Figure 10 or Table 13 instead.

Example 9. What pressure drop should be used for the steam piping of a system if the measured length of the longest run is 500 ft, and the initial pressure must not exceed 2 psig?

Solution: It is assumed, if the measured length of the longest run is 500 ft, that when the allowance for fittings is added, the equivalent length of run does not exceed 1000 ft. Then, with the pressure drop not over one-half of the initial pressure, the drop could be 1 psi or less. With a pressure drop of 1 psi and a length of run of 1000 ft, the drop per 100 ft would be 0.1 psi; if the total drop were 0.5 psi, the drop per 100 ft would be 0.05 psi. In both cases, the pipe could be sized for a desired capacity according to the 0.1 and 0.05 pressure drop lines in Figure 10.

On completion of the sizing, the drop could be checked by taking the longest line and actually calculating the equivalent length of run from the pipe sizes determined. If the calculated drop is less than that assumed, the pipe size is adequate; if it is more, probably an unusual number of fittings is involved, and either the lines must be straightened or the column for the next lower drop must be used and the lines resized. Ordinarily, resizing is unnecessary.

HIGH-PRESSURE STEAM PIPING

Many heating systems for large industrial buildings use high-pressure steam (15 to 150 psig). These systems usually have unit heaters or large built-up fan units with blast heating coils. Temperatures are controlled by a modulating or throttling thermostatic valve or by face or bypass dampers controlled by the room air temperature, fan inlet, or fan outlet.

Figures 10a through 10d present charts for sizing steam piping for systems of 30, 50, 100, and 150 psig at various pressure drops. These charts are based on the Moody friction factor, which considers the Reynolds number and the roughness of the internal pipe surfaces, and contains the same information as the basic chart (Figure 10) but in a more convenient form.

Use of Basic and Velocity Multiplier Charts

Example 10.

Given:
Flow rate = 6700 lb/h
Initial steam pressure = 100 psig
Pressure drop = 11 psi/100 ft

Find:
Size of Schedule 40 pipe required
Velocity of steam in pipe

Solution: The following steps are illustrated by the broken line on Figures 10 and 11.

1. Enter Figure 10 at a flow rate of 6700 lb/h and move vertically to the horizontal line at 100 psig.
2. Follow along inclined multiplier line (upward and to the left) to horizontal 0 psig line. The equivalent weight flow at 0 psig is about 2500 lb/h.
3. Follow the 2500 lb/h line vertically until it intersects the horizontal line at 11 psi per 100 ft pressure drop. Nominal pipe size is 2.5 in. The equivalent steam velocity at 0 psig is about 32,700 fpm.
4. To find the steam velocity at 100 psig, locate the value of 32,700 fpm on the ordinate of the velocity multiplier chart (Figure 11) at 0 psig.

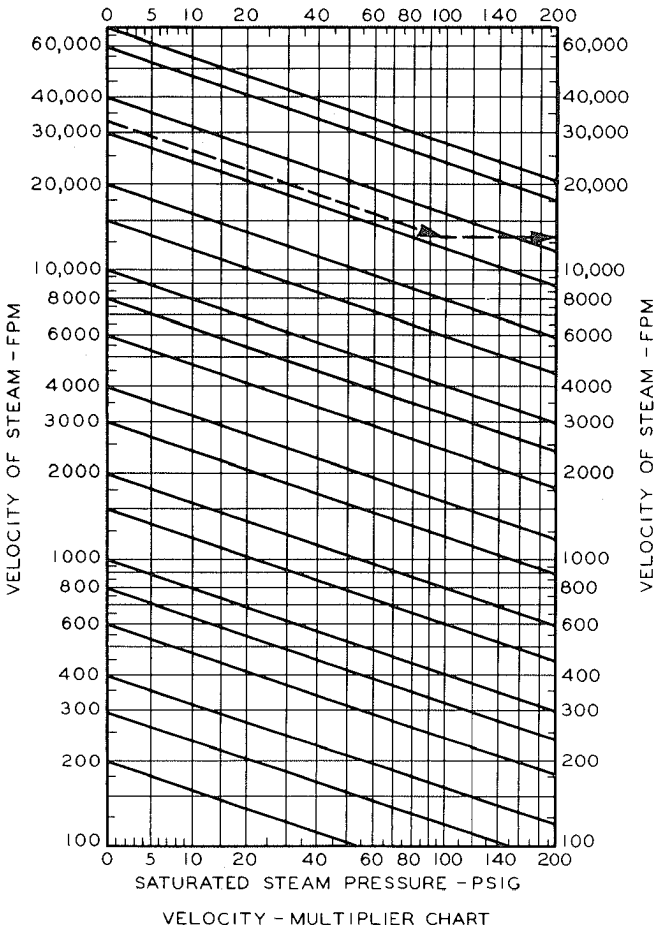

Fig. 11 Velocity Multiplier Chart for Figure 10

5. Move along the inclined multiplier line (downward and to the right) until it intersects the vertical 100 psig pressure line. The velocity as read from the right (or left) scale is about 13,000 fpm.

Note: Steps (1) through (5) would be rearranged or reversed if different data were given.

TWO-PIPE STEAM SYSTEMS

Condensate from steam heating devices is generally saturated liquid or slightly subcooled liquid. The amount of subcooling is a function of the size of the heating device in comparison to the heating load, the control system for the heating device, and the size of the trap and return piping. In properly designed systems, the subcooling is usually no greater than a few degrees. This condensate then passes through a steam trap where the pressure is reduced and some of the liquid may flash into vapor. The amount of flashing depends on the overall pressure drop through the trap, the amount of subcooling in the steam heating device, and the type and condition of the trap.

The process of the fluid passing through the steam trap is a throttling or constant enthalpy process. The resulting fluid on the downstream side of the trap can be a mixture of saturated liquid and vapor. The overall pressure drop and resulting flash vapor are the physical characteristics that differentiate condensate pipe sizing from other types of pipe sizing where only a single phase exists. For this reason, it is important to understand the condition of the condensate when it enters the return line from the trap.

The condition of the condensate downstream of the trap can be expressed by the quality x, defined by:

$$x = \frac{m_v}{m_l + m_v} \tag{11}$$

where

m_v = mass of saturated vapor in condensate
m_l = mass of saturated liquid in condensate

Likewise, the volume fraction V_c of the vapor in the condensate is expressed by:

$$V_c = \frac{V_v}{V_l + V_v} \tag{12}$$

where

V_v = volume of saturated vapor in condensate
V_l = volume of saturated liquid in condensate

The quality and the volume fraction of the condensate downstream of the trap can be estimated from Equations (13) and (14), respectively.

$$x = \frac{h_1 - h_{f_2}}{h_{g_2} - h_{f_2}} \tag{13}$$

$$V_c = \frac{xV_{g_2}}{V_{f_2}(1 - x) + xV_{g_2}} \tag{14}$$

where

h_1 = enthalpy of liquid condensate entering trap evaluated at supply pressure for saturated condensate or at saturation pressure corresponding to temperature of subcooled liquid condensate
h_{f_2} = enthalpy of saturated liquid at return or downstream pressure of trap
h_{g_2} = enthalpy of saturated vapor at return or downstream pressure of trap
V_{f_2} = specific volume of saturated liquid at return or downstream pressure of trap
V_{g_2} = specific volume of saturated vapor at return or downstream pressure of trap

Table 17 presents some values for quality and volume fraction for typical supply and return pressures in heating and ventilating systems. Note that the percent of vapor on a mass basis x is small, while the percent of vapor on a volume basis V_c is very large. This indicates that the return pipe cross section is predominantly occupied by vapor. Figure 12 is a working chart to determine the quality of the condensate entering the return line from the trap for various combinations of supply and return pressures. If the liquid is subcooled entering the trap, the saturation pressure corresponding to the liquid temperature should be used for the supply or upstream pressure. Typical pressures in the return line are given in Table 18.

Condensate return systems can be either *wet* or *dry*, *open* or *closed*. In *wet return systems*, the return pipe contains only the liquid phase and no flash vapor. This occurs when the condensate entering the trap is sufficiently subcooled or when the liquid and vapor are separated and the wet return line is kept below the boiler water line so that liquid only flows through the line. In *dry return systems*, the condensate piping contains both saturated liquid and saturated vapor. This is typical of most condensate return systems. An *open return system* is vented to the atmosphere, and the condensate line is essentially at atmospheric pressure. The driving force for returning the condensate is gravitational acceleration, and the return line must be sloped. In the *closed return system*, the pressure in the condensate return line is above or below atmospheric pressure and is not vented to the atmosphere. The driving force for returning the condensate is a pressure loss along the return line. These types of systems are illustrated in Figure 13.

For the *wet-closed return* where the condensate return line is horizontal, the Darcy-Weisbach Equation (1) for closed conduit flow can be used (Howell 1985). The section Pressure Drop Equa-

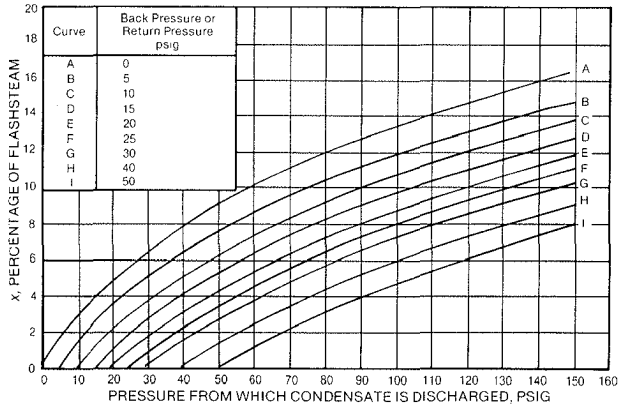

Fig. 12 Working Chart for Determining Percent of Flash Steam (Quality)

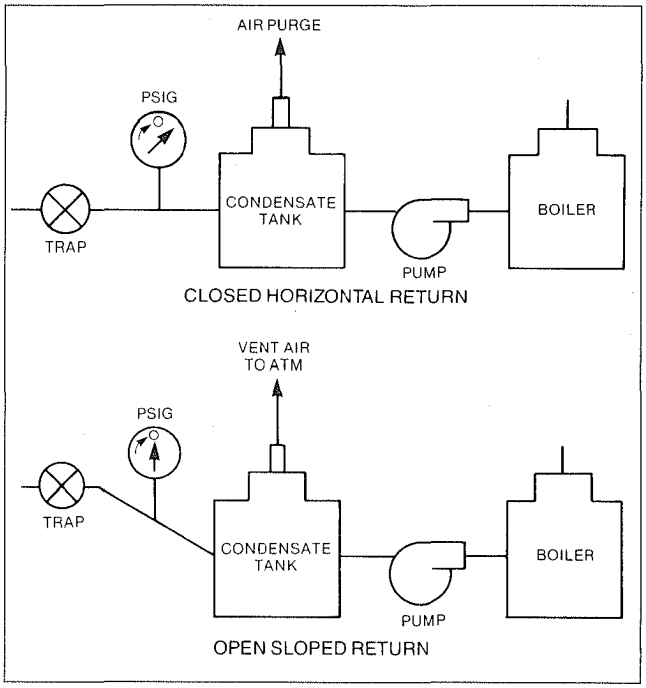

Fig. 13 Types of Condensate Return Lines

tions describes how to apply this equation to full-closed conduits. This equation can be applied to horizontal pipes completely filled with liquid or with vapor. A design pressure loss per unit length ($\Delta p/L$) is usually assumed and then, knowing the design mass flow rate required for the heating device, the required pipe size can be determined by trial and error. Often, a chart such as Figure 1 (where f is assumed constant) can be used to avoid the trial and error solution. Typical design pressure losses per unit length ($\Delta p/L$) are in the range of 1/16 to 1 psi/100 ft. The velocity for liquid condensate systems should not exceed 150 ft/min; for vapor systems, it should not exceed 7000 ft/min.

For the *wet-open return system* with sloped return pipes, the open channel Manning Equation (15) can be used.

$$Q = 1.49\, A r^{2/3} S^{1/2}/n \qquad (15)$$

where

Q = volumetric flow rate, ft^3/s
A = cross-sectional area of conduit, ft^2
r = hydraulic radius of conduit, ft
n = coefficient of roughness (usually = 0.012)
S = slope of conduit, ft/ft

For the wet return, the pipe would be full of liquid. Howell (1985) showed that an equivalency between horizontal pipe flows and sloped pipe flows can be made by assuming that the increase in head due to the slope is equal to the friction loss of the fluid in the pipe. Table 19 gives this equivalency between sloped and horizontal flows. For a wet-open system with a sloped return pipe, the slope used yields the pressure loss from Table 19. Then, the same procedure as for the wet-closed return described earlier can be used to size the sloped condensate return. A constant or appropriate slope in the installed system is difficult to ensure, however.

Table 19 Equivalency between Sloped and Horizontal Flows

Pipe Slope in 10 ft	Pressure Loss, psi/100 ft
1/2 in.	0.180
1 in.	0.361
1-1/2 in.	0.540
2 in.	0.722
3 in.	1.084
4 in.	1.440
5 in.	1.805

When a dry return is *open* and the pipe is sloped, a reasonable procedure can be used to size the return pipe (Howell 1985). When the pipe contains both liquid and vapor, it would run at least at a depth of flow of 0.3 times the pipe diameter. For this conservative situation, the pipe slope should be selected as 1 in. in 10 ft; then the equivalent pressure loss (0.36 psi/100 ft) from Table 19 should be selected for sizing the return pipe at the given heater condensate flow rate. The same procedure described for the wet-closed return is used to size the pipe.

For a *dry-closed* return line with horizontal pipe, which is common, Howell (1985) developed another procedure. Here the *condensate is assumed all vapor*, since V_c is large (0.96 to 0.99). Equation (1) is used to determine the velocity of the vapor in the pipe when the Moody friction factor is used for f. This trial and error procedure starts with a specific $\Delta p/L$ and pipe diameter D, and assumes a value for f. The velocity can then be found from Equation (1). A Reynolds number is found for this velocity and pipe diameter. For the relative roughness and Reynolds number, the friction factor is found from the Moody chart in Chapter 2. If it does not agree with the assumed value, a new f is tried until they do agree.

Once the velocity is determined, the continuity equation is used to find the quantity of vapor moving through the pipe of diameter

[a] For these sizes and pressure losses, the velocity is above 7000 fpm. Select another combination of size and pressure loss.

D. This vapor flow is then divided by the quality x in the condensate line to determine the total (vapor and liquid) condensate flowing in the return pipe. This method assumes that the condensate flows at a uniform average density through the pipe.

This procedure was used to develop several tables that can be used for sizing the condensate return line. For a given supply pressure to the trap and a return line pressure along with an assumed pressure drop per 100 ft ($\Delta p/L$), and knowing the condensate flow rate for the heating device, the proper pipe diameter can be selected from Table 20.

Example 11. A condensate return system has the steam supply at 30 psig, and the return line is nonvented and at 0 psig. The return line is to be horizontal and is to have the capacity for returning 2000 lb/h of condensate. What must the size of the return line be?

Solution: Since the system will be throttling the condensate from 30 psig to 0 psig, there will be flash steam (assuming no subcooling), and the system will be a dry-closed return with a horizontal pipe. The data in Table 19 can be used. A pressure drop of 1/4 psi per 100 ft is selected. In Table 20, for a 30 psig supply and a 0 psig return for $\Delta p/L = 1/4$, a pipe size for the return line of 2 in. is selected.

Example 12. A condensate return system has the steam supply at 100 psig, and the return line is nonvented and at 0 psig. The return line is horizontal and must have a capacity of 2500 lb/h. What size pipe is required?

Solution: Since the system will be throttling non-subcooled condensate from 100 psig to 0 psig, there will be flash steam, and the system will be a dry-closed return with horizontal pipe. Selecting a pressure drop of 1 psi/100 ft yields from Table 20 a nonrecommended situation. Select a pressure drop of 1/4 psi/100 ft, and a 2-1/2 in. pipe can be used for this system.

Example 13. A condensate return system is vented and passes subcooled liquid to the return line. The liquid in the return is at 180°F, and the flow rate must be 1000 lb/h. The return line will be installed with a slope of 1-1/2 in. per 10 ft. What size return line is needed?

Solution: This system is a wet-open condensate return. From Table 19, the equivalent pressure loss for a slope of 1-1/2 in. in 10 ft is 0.54 psi/100 ft. Converting the 1000 lb/h to volume flow (gal/min) yields:

$$1000 \text{ lb/h} \times 0.01651 \text{ ft}^3/\text{lb} \times 7.48 \text{ gal/ft}^3/(60 \text{ m/h}) = 2.06 \text{ gpm}$$

Converting the pressure drop to head loss yields

$$\frac{\Delta h}{100 \text{ ft}} = 0.54 \times \frac{\text{psi}}{100 \text{ ft}} \times 2.307 \frac{\text{ft water}}{\text{psi}} = 1.24 \frac{\text{ft}}{100 \text{ ft}}$$

$$\Delta h/100 \text{ ft} = 0.54 \text{ psi}/100 \text{ ft} \times 2.307 \text{ ft water/psi}$$
$$= 1.24 \text{ ft}/100 \text{ ft of pipe}$$

Figure 1 shows a 1 in. schedule 40 pipe for $\Delta h/100$ ft = 1.24 at 2.06 gpm.

ONE-PIPE STEAM SYSTEMS

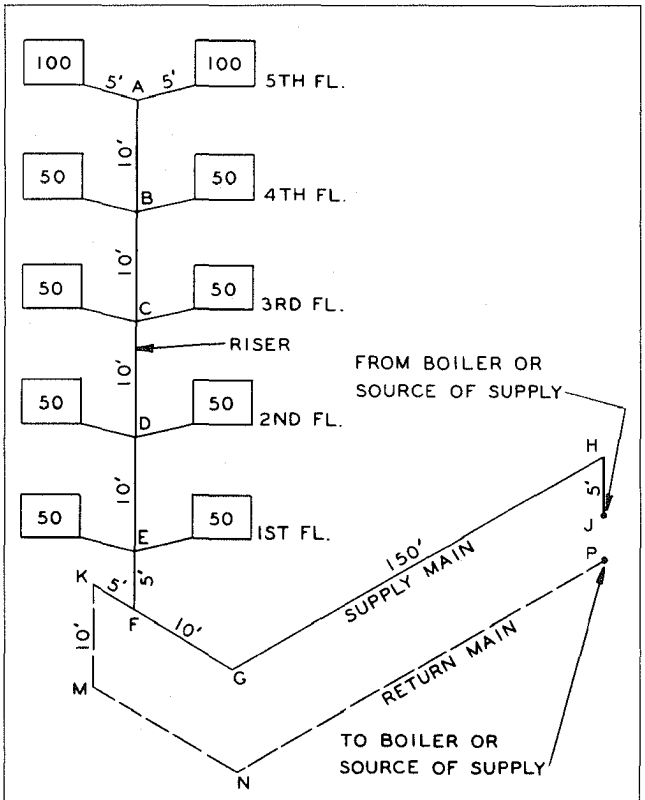
Gravity one-pipe air-vent systems, in which the equivalent length of run does not exceed 200 ft, should be sized using Tables 14, 15, and 16 and Figure 10 as follows:

1. For the *steam main* and *dripped runouts to risers*, where the steam and condensate flow in the same direction, use 1/16 psi drop per 100 ft (Table 14).
2. Where the *riser runouts are not dripped* and the steam and condensate flow in opposite directions, and for the *radiator runouts* with the same condition, use Table 15, Column *F*.
3. For *up-feed steam risers* carrying condensate back from the radiators, use Table 15, Column *D*.
4. For *down-feed systems*, the *main risers* of which do not carry any radiator condensate, use Table 15, Column *B*.
5. For the *radiator valve* size and the *stub connection*, use Table 15, Column *E*.
6. For the *dry-return main*, use Table 16, Column *O*.
7. For the *wet-return main*, use Table 16, Column *N*.

Notes on Gravity One-Pipe Air Vent Systems

1. Pitch of mains should not be less than 0.25 in. in 10 ft.
2. Pitch of horizontal runouts to risers and radiators should not be less than 0.5 in/ft. Where this pitch cannot be obtained, runouts over 8 ft in length should be one size larger than specified in the table.
3. In general, it is not desirable for a main to be less than 2 in. The diameter of the far end of the supply main should not be less than one-half its diameter at its largest part.
4. Supply mains, runouts to risers, or risers should be dripped where necessary.
5. Where supply mains are decreased in size they should be dripped or provided with eccentric couplings, flush on the bottom.

Example 14. Size the one-pipe gravity steam system shown in Figure 14, assuming that this is all there is to the system or that the riser and main shown involve the longest run on the system.



Part of System	Section of Pipe	Radiation Supplied EDR, ft²	Theoretical Pipe Size, in.	Practical Pipe Size, in.
Branches to radiators	—	100	2	2
Branches to radiators	—	50	1-1/4	1-1/4
Riser	A to B	200	2	2
Riser	B to C	300	2-1/2	2-1/2
Riser	C to D	400	2-1/2	2-1/2
Riser	D to E	500	3	3
Riser	E to F	600	3	3
Runout to riser	F to G	600	3	3
Supply main	G to H	600	3	3
Branch to supply main	H to J	600	2-1/2	3
Dry return main	F to K	600	1-1/4	2
Wet return main	K to M	600	1	2
Wet return main	M to N	600	1	2
Wet return main	N to P	600	1	2

Note: EDR = Equivalent direct radiation

Fig. 14 Riser, Supply Main, and Return Main of One-Pipe System

Solution: The total length of run shown is 215 ft. If the equivalent length of the run is double this, it will be 430 ft, and with a total drop of 1/4 psi, the drop per 100 ft will be slightly less than 1/16 psi. In this case, if 1/24 psi is used, the theoretical changes in Table 13 will result. However, these theoretical sizes should be modified by using a wet return not less than 2 in. The main supply, *G-H*, if it is from the uptake of a boiler, should be the full size of the main, or 3 in. The *K-M* portion of the main should be 2 in. if the wet return is also 2 in.

On systems exceeding an equivalent length of 200 ft, total drop should not be over 0.25 psi. The return piping sizes should correspond with the drop used on the steam side of the system. Thus, where a 1/24 psi per 100 ft drop is used, the steam main and dripped runouts are sized from Figure 10, radiator runouts and undripped riser runouts from Table 15, Column *F*. Up-feed risers are sized from Column *D*. The main riser on a downfeed system is sized from Figure 10. (Note that if Column *E* is used, the drop exceeds 1/24 psi per 100 ft.) The dry return is sized from Table 16, Column *L*, and the wet return from Column *K*.

With a 1/32 psi per 100 ft drop, the sizing is the same as for 1/24 psi, except that the steam mean and dripped runouts are sized from Figure 10, the main riser on a down-feed system from Figure 10, the dry return from Column *I*, and the wet return from Column *H*.

GAS PIPE SIZING

Piping for gas appliances should be of adequate size and installed so that it provides a supply of gas sufficient to meet the maximum demand without undue loss of pressure between the point of supply (the meter) and the appliance. The size of gas pipe required depends on (1) maximum gas consumption to be provided, (2) length of pipe and number of fittings, (3) allowable loss in pressure from the outlet of the meter to the appliance, and (4) specific gravity of the gas.

Gas consumption in ft^3/h is obtained by dividing the Btu input rate at which the appliance is operated by the average Btu heating value per ft^3 of the gas. Insufficient gas flow from excessive pressure losses in gas supply lines can cause inefficient operation of gas-fired appliances and sometimes create hazardous operations. Gas-fired appliances are normally equipped with a data plate giving information on maximum gas flow requirements or Btu input as well as inlet gas pressure requirements. The gas utility in the area of installation can give the gas pressure available at the utilities gas meter. Using the information, the required size of gas piping can be calculated for satisfactory operation of the appliance(s).

Table 21 gives pipe capacities for gas flow for up to 200 ft of pipe based on a specific gravity of 0.60. Capacities for pressures less than 1.5 psig may also be determined by the following equation from NFPA *Standard* 54-1988:

$$Q = 2313 d^{2.623} (\Delta p / CL)^{0.541} \quad (16)$$

where

Q = flow rate at 60°F and 30 in. Hg, ft^3/h
d = inside diameter of pipe, in.
Δp = pressure drop, in. of water
C = factor for viscosity, density, and temperature
$= 0.00354(t + 460)s^{0.848}\mu^{0.152}$
t = temperature, °F
s = ratio of density of gas to density of air at 60°F and 30 in. Hg
μ = viscosity of gas, centipoise (0.012 for natural gas, 0.008 for propane)
L = pipe length, ft

Gas service in buildings is generally delivered in the "low-pressure" range of 7 in of water. The maximum pressure drop allowable in piping systems at this pressure is generally 0.5 in. of water, but is subject to regulation by local building, plumbing, and gas appliance codes (see also the *National Fuel Gas Code*, NFPA 54).

Where large quantities of gas are required or where long lengths of pipe are used, as in industrial buildings, low-pressure limitations result in large pipe sizes. Local codes may allow and local gas companies may deliver gas at higher pressures (*e.g.*, 2, 5, or 10 psig). Under these conditions, an allowable pressure drop of 10% of the initial pressure is used, and pipe sizes can be reduced significantly. Gas pressure regulators at the appliance must be specified to accommodate higher inlet pressures. NFPA (1988) provides information on pipe sizing for various inlet pressures and pressure drops at higher pressures.

More complete information on gas piping can be found in the *Gas Engineers' Handbook* (1970).

FUEL OIL PIPE SIZING

The pipe used to convey fuel oil to oil-fired appliances must be large enough to maintain low pump suction pressure and, in the case of circulating loop systems, to prevent overpressure at the burner oil pump inlet. Pipe materials must be compatible with the fuel and must be carefully assembled to eliminate all leaks. Leaks in suction lines cause pumping problems that result in unreliable burner operation. Leaks in pressurized lines create fire hazards. Cast-iron or aluminum fittings and pipe are unacceptable. Pipe joint compounds must be selected carefully.

Oil pump suction lines should be sized so that at maximum suction line flow conditions, the maximum vacuum will not exceed 10 in. Hg for distillate grade fuels and 15 in. Hg for residual oils. Oil supply lines to burner oil pumps should not be pressurized by circulating loop systems or aboveground oil storage tanks to more than 5 psi, or pump shaft seals may fail. A typical oil circulating loop system is shown in Figure 15.

In assembling long fuel pipe lines, care should be taken to avoid air pockets. On overhead circulating loops, the line should vent air at all high points. Oil supply loops for one or more burners should

Notes: 1. Capacity is in cubic feet per hour at gas pressures of 0.5 psig or less and a pressure drop of 0.5 in. of water; Specific gravity = 0.60.

2. Copyright by the American Gas Association and the National Fire Protection Association. Used by permission of the copyright holder.

be the continuous circulation type, with excess fuel returned to the storage tank. Dead-ended pressurized loops can be used, but air or vapor venting is more problematic.

Where valves are used, select ball or gate valves. Globe valves are not recommended because of their high pressure drop characteristics.

Oil lines should be tested after installation, particularly if they are buried, enclosed, or otherwise inaccessible. Failure to perform this test is a frequent cause of later operating difficulties. A suction line can be hydrostatically tested at 1.5 times its maximum operating pressure or at a vacuum of not less than 20 in. Hg. Pressure or vacuum tests should continue for at least 60 min. If there is no noticeable drop in the initial test pressure, the lines can be considered tight.

Pipe Sizes for Heavy Oil

Tables 22 and 23 give recommended pipe sizes for handling No. 5 and No. 6 oils (residual grades) and No. 1 and No. 2 oils (distillate grades), respectively.

Storage tanks and piping and pumping facilities for delivering the oil from the tank to the burner are important considerations in the design of an industrial oil-burning system. The construction and location of the tank and oil piping are usually subject to local regulations and the National Fire Protection Association's *Flammable and Combustible Fuels Code* and *Standard* 31.

Table 22 Recommended Nominal Size for Fuel Oil Suction Lines from Tank to Pump (Residual Grades, Numbers 5 and 6)

Pumping Rate, gal/h	Length of Run in Feet at Maximum Suction Lift = 15 ft									
	25	50	75	100	125	150	175	200	250	300
10	1-1/2	1-1/2	1-1/2	1-1/2	1-1/2	1-1/2	2	2	2-1/2	2-1/2
40	1-1/2	1-1/2	1-1/2	2	2	2-1/2	2-1/2	2-1/2	2-1/3	3
70	1-1/2	2	2	2	2	2-1/2	2-1/2	2-1/2	3	3
100	2	2	2	2-1/2	2-1/2	3	3	3	3	3
130	2	2	2-1/2	2-1/2	2-1/2	3	3	3	3	4
160	2	2	2-1/2	2-1/2	2-1/2	3	3	3	4	4
190	2	2-1/2	2-1/2	2-1/2	3	3	3	4	4	4
220	2-1/2	2-1/2	2-1/2	3	3	3	4	4	4	4

Notes: 1. Pipe sizes smaller than 1 in. IPS are not recommended for use with residual grade fuel oils.
2. Lines conveying fuel oil from pump discharge port to burners and tank return may be reduced by 1 or 2 sizes, depending on piping length and pressure losses.

Table 23 Recommended Nominal Size for Fuel Oil Suction Lines from Tank to Pump (Distillate Grade Numbers 1 and 2)

Pumping Rate, gal/h	Length of Run in Feet at Maximum Suction Lift = 10 ft									
	25	50	75	100	125	150	175	200	250	300
10	1/2	1/2	1/2	1/2	1/2	1/2	1/2	3/4	3/4	1
40	1/2	1/2	1/2	1/2	1/2	3/4	3/4	3/4	3/4	1
70	1/2	1/2	3/4	3/4	3/4	3/4	3/4	1	1	1
100	1/2	3/4	3/4	3/4	3/4	1	1	1	1	1-1/4
130	1/2	3/4	3/4	1	1	1	1	1	1-1/4	1-1/4
160	3/4	3/4	3/4	1	1	1	1	1-1/4	1-1/4	1-1/4
190	3/4	3/4	1	1	1	1	1-1/4	1-1/4	1-1/4	2
220	3/4	1	1	1	1	1-1/4	1-1/4	1-1/4	1-1/4	2

CHAPTER 34

ABBREVIATIONS AND SYMBOLS

Abbreviations for Texts, Drawings, and Computer Programs 34.1
Letter Symbols 34.1
Dimensionless Numbers 34.4
Mathematical Symbols and Subscripts 34.5
Graphical Symbols for Drawings 34.5
Piping System Identification 34.12

THIS chapter contains information about abbreviations and symbols for heating, ventilating, refrigerating, and air-conditioning engineers.

Abbreviations are shortened forms of names and expressions used in drawings, texts, and computer programs. This chapter discusses conventional English language abbreviations that may be different in other languages. A *letter symbol* represents a quantity or a unit, not its name, and is independent of language. Because of this, use of a letter symbol is preferred over abbreviations for unit or quantity terms. Letter symbols necessary for individual chapters are defined in the chapters where they occur.

Abbreviations are never used when a mathematical sign is involved, such as the equality sign (=) or division sign (/), except in computer programming, where the abbreviation takes on the function of a letter symbol. Mathematical operations are performed only with symbols. Abbreviations should be used only where necessary to save time and space; avoid their usage in documents circulated in foreign countries.

Graphical symbols in this chapter are easy to draw and recognize and were selected to save engineering drafting time. Symbols of piping, ductwork, fittings, and in-line accessories can be used on scale drawings and diagrams.

Identifying piping by legend and color promotes greater safety and lessens the chance of error in emergencies. Piping identification is now required throughout the United States by the Occupational Safety and Health Act (OSHA) for some industries and by many federal, state, and local codes.

ABBREVIATIONS FOR TEXTS, DRAWINGS, AND COMPUTER PROGRAMS

Abbreviations for text and drawings have been compiled from *Abbreviations for Use on Drawings and in Text*, ANSI Y1.1-72. Table 1 gives some of these abbreviations, as well as others commonly found on mechanical drawings and abbreviations (symbols) used in computer programming.

Abbreviations specific to a single subject are defined in the chapters in which they appear. Additional abbreviations used on drawings can be found in the Graphical Symbols section of this chapter.

The abbreviations (symbols) used for computer programming for the heating, ventilating, refrigerating, and air-conditioning industries have been developed by ASHRAE Technical Committee 1.5, Computer Applications. These symbols identify computer variables, subprograms, subroutines, and functions commonly applied in the industry. Use of these symbols enhances comprehension of the program listings and provides a clearly defined nomenclature in applicable computer programs.

Certain programming languages differentiate between *real numbers* (numbers with decimals) and *integers* (numbers without decimals). This is done by reserving certain initial letters of a variable for integer numbers. For instance, in Fortran, any variable beginning with the letters H through N is defined by the computer as an integer. Many of the symbols listed in this chapter begin with these letters and, in order to make them real numbers, must be prefixed with a noninteger letter. Thus, HP would become XHP if the programmer wanted to define horsepower as a decimal value.

Many symbols have two or more options listed. The longest abbreviation is the preferred one and should be used if possible. However, it is sometimes necessary to shorten the symbol to further identify the variable. For instance, the area of a wall cannot be defined as WALLAREA because most computer languages restrict the number of letters in a variable name. Therefore, a shorter variable symbol is applied, and WALLAREA becomes WALLA or WAREA.

In Table 1, the same symbol is sometimes used for different terms. This liberty is taken because it is highly unlikely that the two terms would be used in the same program. If such were the case, one of the terms would require a suffix or prefix to differentiate it from the other.

LETTER SYMBOLS

Letter symbols include symbols for physical quantities (quantity symbols) and symbols for the units in which these quantities are measured (unit symbols). *Quantity symbols*, such as *I* for electric current, are listed in this chapter and are printed in italic type. A *unit symbol* is a letter or group of letters such as mm for millimetre, or a special sign such as ° for degrees, and is printed in Roman type. Subscripts and superscripts are governed by the same principles. Letter symbols are restricted mainly to the English and Greek alphabets.

Quantity symbols may be used in mathematical expressions in any way consistent with good mathematical usage. The product of two quantities, a and b, is indicated by ab. The quotient is a/b, or ab^{-1}. To avoid misinterpretation, parentheses must be used if more than one slash (/) is employed in an algebraic term, *e.g.*, ($a/b/c$ or $a/b/c$), but not $a/b/c$.

Subscripts and superscripts, or several of them separated by commas, may be attached to a single basic letter (kernel), but not to other subscripts or superscripts. A symbol that has been modified by a superscript should be enclosed in parentheses before an exponent is added $(X_a)^3$. Symbols can also have alphanumerical marks such as ′ (prime), ⁺ (plus), and * (asterisk).

More detailed information on the general principles of letter symbol standardization can be found in *IEEE Standard Letter Symbols for Units of Measurement* (ANSI/IEEE *Standard* 260-78) and *Glossary of Terms Concerning Letter Symbols* (ASME Y10.1-72), the source of the above paragraphs.

The letter symbols have, in general, been taken from the following American National Standards Institute (ANSI) standards:

Y10.3M-84 *Letter Symbols for Mechanics and Time-Related Phenomena*

The preparation of this chapter is assigned to TC 1.6, Terminology

Table 1 Abbreviations for Text, Drawings, and Computer Programming

Term	Text	Drawings	Program
above finished floor	—	AFF	—
absolute	abs	ABS	ABS
accumulat(e, -or)	acc	ACCUM	ACCUM
air condition(-ing, -ed)	—	AIR COND	—
air-conditioning unit(s)	—	ACU	ACU
air-handling unit	—	AHU	AHU
air horsepower	ahp	AHP	AHP
alteration	altrn	ALTRN	—
alternating current	ac	AC	AC
altitude	alt	ALT	ALT
ambient	amb	AMB	AMB
American National Standards Institute[1]	ANSI	ANSI	—
American wire gage	AWG	AWG	—
ampere (amp, amps)	Amp	AMP	AMP, AMPS
angle	—	—	ANG
angle of incidence	—	—	ANGI
apparatus dew point	adp	ADP	ADP
approximate	approx	APPROX	—
area	—	—	A
atmosphere	atm	ATM	—
average	avg	AVG	AVG
azimuth	az	AZ	AZ
azimuth, solar	—	—	SAZ
azimuth, wall	—	—	WAZ
barometer(-tric)	baro	BARO	—
bill of material	b/m	BOM	—
boiling point	bp	BP	—
brake horsepower	bhp	BHP	BHP
Brown & Sharpe wire gage	B&S	B&S	—
British thermal unit	Btu	BTU	BTU
Btu per hour (thousand)	Mbh	MBH	MBH
center to center	c to c	C TO C	—
circuit	ckt	CKT	CKT
clockwise	cw	CW	—
coefficient	coef	COEF	COEF
coefficient, valve flow	C_v	C_v	C_v
coil	—	—	COIL
compressor	cprsr	CMPR	CMPR
condens(-er, -ing, -ation)	cond	COND	COND
conductance	—	—	C
conductivity	cndct	CNDCT	K
conductors, number of (3)	3/c	3/c	—
contact factor	—	—	CF
cooling load	clg load	CLG LOAD	CLOAD
counterclockwise	ccw	CCW	—
cubic feet	cu ft	CU FT	CUFT, CFT
cubic inch	cu in	CU IN	CUIN, CIN
cubic feet per minute	cfm	CFM	CFM
cfm, standard conditions	scfm	SCFM	SCFM
cu ft per sec, standard	scfs	SCFS	SCFS
Daylight Saving Time	DST	DST	DST
decibel	dB	DB	DB
degree	deg or 1	DEG or 1	DEG
density	dens	DENS	RHO
depth or deep	dp	DP	DPTH
dew-point temperature	dpt	DPT	DPT
diameter	dia	DIA	DIA
diameter, inside	id	ID	ID
diameter, outside	od	OD	OD
difference or delta	diff	DIFF	D, DELTA
diffuse radiation	—	—	DFRAD
direct current	dc	DC	DC
direct radiation	dir radn	DIR RADN	DIRAD
dry	—	—	DRY
dry-bulb temperature	dbt	DBT	DB, DBT
effectiveness	—	—	EFT
effective temperature[2]	ET*	ET*	ET
efficiency	eff	EFF	EFF
efficiency, fin	—	—	FEFF
efficiency, surface	—	—	SEFF
electromotive force	emf	EMF	—
elevation	el	EL	ELEV
entering	entr	ENT	ENT
entering water temperature	ENT	ENT	ENT
entering air temperature	EAT	EAT	EAT
enthalpy	—	—	H
entropy	—	—	S
equivalent direct radiation	edr	EDR	—
equivalent feet	eqiv ft	EQIV FT	EQFT
equivalent inches	eqiv in	EQIV IN	EQIN
evaporat(-e, -ing, -ed, -or)	evap	EVAP	EVAP
expansion	exp	EXP	XPAN
face area	fa	FA	FA
face to face	f to f	F to F	—
face velocity	fvel	FVEL	FV
factor, correction	—	—	CFAC, CFACT
factor, friction	—	—	FFACT, FF
Fahrenheit	F	F	F
fan	—	—	FAN
feet per minute	fpm	FPM	FPM
feet per second	fps	FPS	FPS
film coefficient, inside	—	—	FI, HI
film coefficient, outside	—	—	FO, HO
flow rate, air	—	—	QAR, QAIR
flow rate, fluid	—	—	QFL
flow rate, gas	—	—	QGA, QGAS
foot or feet	ft	FT	FT
foot pound	ft lb	FT LB	—
freezing point	fp	FP	FP
frequency	Hz	HZ	—
gage or gauge	ga	GA	GA, GAGE
gallons	gal	GAL	GAL
gallons per hour	gph	GPH	GPH
gph, standard	std gph	SGPH	SGPH
gallons per day	gpd	GPD	GPD
grains	gr	GR	GR
gravitational constant	g	G	G
greatest temp difference	gtd	GTD	GTD
head	hd	HD	HD
heat	—	—	HT
heater	—	—	HTR
heat gain	HG	HG	HG, HEATG
heat gain, latent	LHG	LHG	HGL
heat gain, sensible	SHG	SHG	HGS
heat loss	—	—	HL, HEATL
heat transfer	—	—	Q
heat transfer coefficient	U	U	U
height	hgt	HGT	HGT, HT
high-pressure steam	hps	HPS	HPS
high-temperature hot water	hthw	HTHW	HTHW
horsepower	hp	HP	HP
hour(s)	hr	HR	HR
humidity, relative	rh	RH	RH
humidity ratio	W	W	W
incident angle	—	—	INANG
indicated horsepower	ihp	IHP	—
International Pipe Std	IPS	IPS	—
iron pipe size	ips	IPS	—
kelvin	K	K	K
kilowatt	kW	KW	KW
kilowatt hour	kWh	KWH	KWH
latent heat	LH	LH	LH, LHEAT
least mean temp difference[4]	lmtd	LMTD	LMTD
least temp difference[4]	ltd	LTD	LTD
leaving air temperature	lat	LAT	LAT
leaving water temperature	lwt	LWT	LWT
length	lg	LG	LG, L
linear feet	lin ft	LF	LF
liquid	liq	LIQ	LIQ
logarithm (natural)	ln	LN	LN
logarithm to base 10	log	LOG	LOG
low-pressure steam	lps	LPS	LPS

low-temp. hot water	lthw	LTHW	LTHW
Mach number	Mach	MACH	—
mass flow rate	mfr	MFR	MFR
maximum	max	MAX	MAX
mean effective temp.	met	MET	MET
mean temp. difference	mtd	MTD	MTD
medium pressure steam	mps	MPS	MPS
medium temp. hot water	mthw	MTHW	MTHW
mercury	HG	HG	HG
miles per hour	mph	MPH	MPH
minimum	min	MIN	MIN
noise criteria	NC	NC	—
normally open	n o	N O	—
normally closed	n c	N C	—
not applicable	n/a	N/A	—
not in contract	n i c	N I C	—
not to scale	—	N T S	—
number	no	NO	N, NO
number of circuits	—	—	NC
number of tubes	—	—	NT
ounce	oz	OZ	OZ
outside air	oa	OA	OA
parts per million	ppm	PPM	PPM
percent	%	%	PCT
phase(electrical)	ph	PH	—
pipe	—	—	PIPE
pounds	lbs	LBS	LBS
pounds per square foot	psf	PSF	PSF
psf absolute	psfa	PSFA	PSFA
psf gage	psfg	PSFG	PSFG
pounds per square inch	psi	PSI	PSI
psi absolute	psia	PSIA	PSIA
psi gage	psig	PSIG	PSIG
pressure	—	PRESS	PRES, P
pressure, barometric	baro pr	BARO PR	BP
critical pressure	—	—	CRIP
pressure, dynamic (velocity)	vp	VP	VP
pressure drop or difference	pd	PD	PD, DELTP
pressure, static	sp	SP	SP
pressure, vapor	vap pr	VAP PR	VAP
primary	pri	PRI	PRIM
quart	qt	QT	QT
radian	—	—	RAD
radiat(-e, -or)	—	RAD	—
radiation	—	RADN	RAD
radius	—	—	R
rankine	R	R	R
receiver	rcvr	RCVR	REC
recirculate	recirc	RECIRC	RCIR, RECIR
refrigerant (12, 22, etc.)	R12, R22	R12, R22	R12, R22
relative humidity	rh	RH	RH
resist(-ance, -ivity, -or)	res	RES	RES
return air	ra	RA	RA
revolutions	rev	REV	REV
revolutions per minute	rpm	RPM	RPM
revolutions per second	rps	RPS	RPS
roughness	rgh	RGH	RGH, E
safety factor	sf	SF	SF
saturation	sat	SAT	SAT
saybolt seconds furol	ssf	SSF	SSF
saybolt seconds universal	ssu	SSU	SSU
sea level	sl	SL	SE
second	sec	SEC	SEC
sensible heat	SH	SH	SH
sensible heat gain	SHG	SHG	SHG
sensible heat ratio	SHR	SHR	SHR
shading coefficient	—	—	SC
shaft horsepower	sft hp	SFT HP	SHP
solar	—	—	SOL
specification	spec	SPEC	—
specific gravity	SG	SG	—
specific heat	SP HT	SP HT	C
sp ht at constant pressure	—	—	CP
sp ht at constant volume	—	—	CV
specific volume	sp vol	SP VOL	V, CVOL
square	sq	SQ	SQ
standard	std	STD	STD
standard time meridian	—	—	STM
static pressure	SP	SP	SP
suction	suct	SUCT	SUCT, SUC
summ(-er, -ary, -ation)	—	—	SUM
supply	sply	SPLY	SUP, SPLY
supply air	SA	SA	SA
surface	—	—	SUR, S
surface, dry	—	—	SURD
surface, wet	—	—	SURW
system	—	—	SYS
tabulat(-e, -ion)	tab	TAB	TAB
tee	—	—	TEE
temperature	temp	TEMP	T, TEMP
temperature difference	TD	TD	TD, TDIF
temperature entering	TE	TE	TE, TENT
temperature leaving	TL	TL	TL, TLEA
thermal conductivity	K	K	K
thermal expansion coef	—	—	TXPC
thermal resistance	R	R	RES, R
thermocouple	tc	TC	TC, TCPL
thermostat	T STAT	T STAT	T STAT
thick(-ness)	thkns	THKNS	THK
thousand circular mils	Mcm	MCM	MCM
thousand cubic feet	Mcf	MCF	MCF
thousand foot lbs	kip ft	KIP FT	KIPFT
thousand pounds	kip	KIP	KIP
time	t	T	T
ton	—	—	TON
tons of refrigeration	tons	TONS	TONS
total	—	—	TOT
total heat	tot ht	TOT HT	—
transmissivity	—	—	TAU
U factor	—	—	U
unit	—	—	UNIT
vacuum	vac	VAC	VAC
valve	v	V	VLV
vapor proof	vap prf	VAP PRF	—
variable	var	VAR	VAR
variable air volume	vav	VAV	VAV
velocity	vel	VEL	VEL, V
velocity, wind	w vel	W VEL	W VEL
ventilation, vent	vent	VENT	VENT
vertical	vert	VERT	VERT
viscosity	visc	VISC	MU, VISC
volt	V	V	E
volt ampere	VA	VA	VA
volume	vol	VOL	VOL

wind pressure	wpr	WPR	WP, WPRES
yard	yd	YD	YD
year	yr	YR	YR
zone	z	Z	Z, ZN

[1] Abbreviations of most proper names use capital letters in both text and drawings.
[2] The asterisk (*) is used with ET*, effective temperature, as in Chapter 8 of this volume.
[3] These are surface heat transfer coefficients.
[4] Letter L also used for *Logarithm of* these temperature differences in computer programming.

Y10.4-82 *Letter Symbols for Heat and Thermodynamics* (Reaffirmed 1988)
260-78 *Letter Symbols for Units of Measurement*, ANSI/IEEE Standard.

When standard symbols in related fields are needed, reference to the following ASME standards is recommended:

Y10.2-58 *Letter Symbols for Hydraulics*
Y10.11-84 *Letter Symbols and Abbreviations for Quantities Used in Acoustics*
Y10.12-55 *Letter Symbols for Chemical Engineering* (Reaffirmed 1988)

Other symbols chosen by an author for a physical magnitude not appearing in any standard list should be ones that do not already have different meanings in the field of the text.

LETTER SYMBOLS

Symbol	Description of Item	Typical Units
A	area	ft^2
a	acoustic velocity	fps or fpm
b	breadth or width	ft
B	barometric pressure	psia or in. Hg
c	concentration	lb/ft^3, mol/ft^3
c	specific heat	Btu/lb · °F
c_p	specific heat at constant pressure	Btu/lb · °F
c_v	specific heat at constant volume	Btu/lb · °F
C	coefficient	—
C	thermal conductance	Btu/h · ft^2 · °F
C	fluid capacity rate	Btu/h · °F
C_L	loss coefficient	—
C_P	coefficient of performance	—
d	prefix meaning differential	—
D or d	diameter	ft
d_e	equivalent or hydraulic diameter	ft
D_v	mass diffusivity	ft^2/s
e	base of natural logarithms	—
E	energy	Btu
E	electrical potential	V
f	film conductance (alternate for h)	Btu/h · ft^2 · °F
f	frequency	Hz
f_D	friction factor, D'Arcy-Weisbach formulation	—
f_F	friction factor, Fanning formulation	—
F	force	lb
F_{ij}	angle factor (radiation)	—
g	gravitational acceleration	ft/s^2
G	mass velocity	lb/h · ft^2
h	heat transfer coefficient	Btu/h · ft^2 · °F
h	hydraulic head	ft
h_D	mass transfer coefficient	lb/h · ft^2 · lb per ft^3
h	specific enthalpy	Btu/lb
h_a	enthalpy of dry air	Btu/lb
h_s	enthalpy of moist air at saturation	Btu/lb
H	total enthalpy	Btu
I	electric current	A
J	mechanical equivalent of heat	ft · lb/Btu
k	thermal conductivity	Btu/h · ft · °F
k (or γ)	ratio of specific heats, c_p/c_v	—
K	proportionality constant	—
K_D	mass transfer coefficient	lb/h · ft^2
l or L	length	ft
L_w	sound power	dB
L_p	sound pressure	dB
m or M	mass	lb
M	molecular weight	lb/lb mol
N	rate of rotation	rpm
N or n	number in general	—
p or P	pressure	psi
p_a	partial pressure of dry air	psi
p_w	partial pressure of water vapor in moist air	psi
p_s	vapor pressure of water in saturated moist air	psi
P	power	hp,watts
q	time rate of heat transfer	Btu/h
Q	volumetric flow rate	cfm
Q	total heat transfer	Btu
r	radius	ft
r or R	thermal resistance	ft^2 · h · °F/Btu
R	gas constant	ft · lb/lb · °R
s	specific entropy	Btu/lb · °R
S	total entropy	Btu/ °R
t	temperature	°F
T	absolute temperature	°R
Δt_m or ΔT_m	mean temperature difference	°F
u	specific internal energy	Btu/lb
U	total internal energy	Btu
U	overall heat transfer coefficient	Btu/h·ft^2 · °F
v	specific volume	ft^3/lb
V	total volume	ft^3
V	linear velocity	fps
w	mass rate of flow	lb/h
W	weight	lb
W	work	ft-lb
W	humidity ratio of moist air	lb (water)/ lb (dry air)
W_s	humidity ratio of moist air at saturation	lb (water)/ ib (dry air)
x	mole fraction	—
x	quality, mass fraction of vapor	—
x,y,z	lengths along principal coordinate axes	ft
Z	figure of merit	—
α	absolute Seebeck coefficient	V/ °C
α	absorptivity, absorptance radiation	—
α	linear coefficient of thermal expansion	per °F

SUBSCRIPTS

These are to be affixed to the appropriate symbols. Several subscripts may be used together to denote combinations of various states, points, or paths. Often the subscript indicates that a particular property is to be kept constant in a process.

$a,b, \ldots$	referring to different phases, states or physical conditions of a substance, or to different substances
a	air
a	ambient
b	barometric (pressure)
c	referring to critical state or critical value
c	convection
db	dry bulb
dp	dew point
e	base of natural logarithms
f	referring to saturated liquid
f	film
fg	referring to evaporation or condensation
F	friction
g	referring to saturated vapor
h	referring to change of phase in evaporation
H	water vapor
i	referring to saturated solid
i	internal
if	referring to change of phase in melting
ig	referring to change of phase in sublimation
k	kinetic
L	latent
m	mean value
M	molar basis
o	referring to initial or standard states or conditions
p	referring to constant pressure conditions or processes
p	potential
r	refrigerant
r	radiant or radiation
s	referring to moist air at saturation
s	sensible
s	referring to isentropic conditions or processes
s	static (pressure)
s	surface
t	total (pressure)
T	referring to isothermal conditions or processes
v	referring to constant volume conditions or processes
v	vapor
v	velocity (pressure)
w	wall
w	water
wb	wet bulb
$1,2, \ldots$	different points in a process, or different instants of time

GRAPHICAL SYMBOLS FOR DRAWINGS

Graphical symbols have been extracted from (1) *Graphic Symbols for Pipe Fittings, Valves, and Piping* [ANSI 232.2.3-1949 (Reaffirmed 1953)]; (2) *Graphic Symbols for Heating, Ventilating, and Air Conditioning* [ASME Y32.2.4-49 (Reaffirmed 1984)]; (3) *American Standard Abbreviations for Use on Drawings and in Text* (ASME Y1.1-72); and (4) *Graphic Symbols for Plumbing Fixtures for Diagrams Used in Architectural and Building Construction* (ASME Y32.4-77).

Some of these symbols have been modified and others have been added to reflect current practice. Symbols and quotations are used with permission of the publisher, The American Society of Mechanical Engineers.

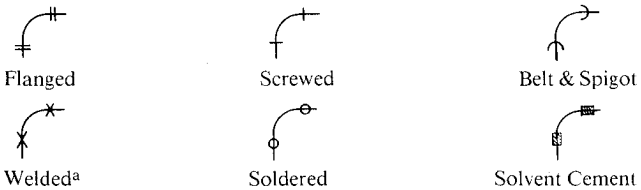
[b] Refer to *Fire Protection Symbols for Architectural and Engineering Drawings* (NFPA *Standard* 172 P-86) for additional symbols.

Fittings

The following fittings are shown with screwed connections. The symbol for the body of a fitting is the same for all types of connections, unless otherwise specified. The types of connections are often specified for a range of pipe sizes, but are shown with the fitting symbol where required. For example, an elbow would be:



Fitting	*Symbol*
Bushing	
Cap	
Connection, Bottom	
Connection, Top	
Coupling (Joint)	
Cross

Electrical Equipment[a]

Symbols for electrical equipment shown on mechanical drawings are usually geometric figures with an appropriate name or abbreviation, with details described in the specifications. The following are some common examples.[b]

Motor Control

Disconnect Switch, Unfused

Disconnect Switch, Fused

Time Clock

Automatic Filter Panel

Lighting Panel

Power Panel

[a] See *Graphic Electrical Symbols for Air-Conditioning and Refrigeration Equipment* (ARI *Standard* 130-82) for preferred symbols of common electrical parts.

[b] Number each symbol if more than one; see *Graphic Symbols for Plumbing Fixtures for Diagrams Used in Architecture and Building Construction* (ANSI Y32.4-77).

PIPING SYSTEM IDENTIFICATION

The material in piping systems is identified to promote greater safety and lessen the chances of error, confusion or inaction in times of emergency. Primary identification should be by means of a lettered legend naming the material conveyed by the piping. In addition to, but not instead of lettered identification, color can be used to identify the hazards or use of the material.

The data has been extracted from the *Scheme for the Identification of Piping Systems,* ASME A13.1-81, with the permission of the publisher, The American Society of Mechanical Engineers.

DEFINITIONS

Piping Systems

Piping systems include pipes of any kind, fittings, valves, and pipe coverings. Supports, brackets, and other accessories are not included. Pipes are defined as conduits for the transport of gases, liquids, semiliquids, or fine particulate dust.

Materials Inherently Hazardous to Life and Property

Flammable or Explosive. Materials that are easily ignited, including materials known as fire producers or explosives.

Chemically Active or Toxic. Materials that are corrosive or are in themselves toxic or productive of poisonous gases.

At Temperatures or Pressures. Materials that, when released from the piping, cause a sudden outburst with the potential for inflicting injury or property damage by burns, impingement, or flashing to vapor state.

Radioactive. Materials that emit ionizing radiation.

Table 2 Examples of Legends

HOT WATER
AIR 100 PSIG
H.P. RETURN
STEAM 100 PSIG

Table 3 Classification of Hazardous Materials and Designation of Colors[a]

Classification	Color Field	Color of Letters for Legend
Materials Inherently Hazardous		
Flammable or Explosive	Yellow	Black
Chemically Active or Toxic	Yellow	Black
Extreme Temperatures or Pressures	Yellow	Black
Radioactive[b]	Purple	Yellow
Materials of Inherently Low Hazard		
Liquid or Liquid Admixture[c]	Green	Black
Gas or Gaseous Admixture	Blue	White
Fire Quenching Materials		
Water, Foam, CO_2, Halon, etc.	Red	White

[a] When the color scheme above is used, the colors should be as recommended in ANSI Z-53.1 latest revision, *Safety Color Code for Marking Physical Hazards.*

[b] Previously specified radioactive markers using yellow or purple are acceptable if already installed and/or until existing supplies are depleted, subject to applicable Federal regulations.

[c] Markers with black letters on a green color field are acceptable if already installed and/or until existing supplies are depleted.

Table 4 Size of Legend Letters

Outside Diameter of Pipe or Covering, in.	Length of Color Field A, in.	Size of Letters B, in.
¾ to 1¼	8	½
1½ to 2	8	¾
2½ to 6	12	1¼
8 to 10	24	2½
over 10	32	3½

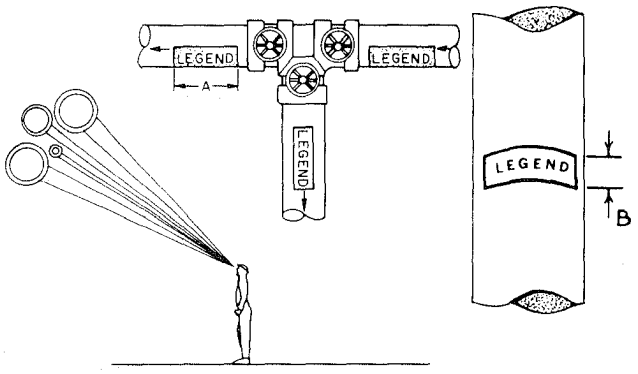

Fig. 1 Visibility of Pipe Markings

Materials of Inherently Low Hazard

All materials that are not hazardous by nature, and are near enough to ambient pressure and temperature that people working on systems carrying these materials run little risk through their release.

Fire Quenching Materials

This classification includes sprinkler systems and other piped fire fighting or fire protection equipment. This includes water (for fire fighting), chemical foam, CO_2, Halon, and so forth.

METHOD OF IDENTIFICATION

Legend

The legend is the primary and explicit identification of content. Positive identification of the content of the piping system is by lettered legend giving the name of the contents, in full or abbreviated form, as shown in Table 2. Arrows are used to indicate the direction of flow. Use the legend to identify contents exactly and to provide temperature, pressure and other details necessary to identify the hazard.

The legend shall be brief, informative, pointed, and simple. Legends should be applied close to valves and adjacent to changes in direction, branches, where pipes pass through walls or floors and as frequently as needed along straight runs to provide clear and positive identification. Identification may be applied by stenciling, tape or markers (see Figure 1). The number and location of identification markers on a particular piping system is based on judgment.

Color

Colors listed in Table 3 are used to identify the characteristic properties of the contents. Color can be shown on or contiguous to the piping by any physical means, but it should be used in combination with a legend. Color can be used in continuous total length coverage or in intermittent displays.

Visibility

Pipe markings should be highly visible. If pipe lines are above the normal line of vision, the lettering is placed below the horizontal centerline of the pipe (Figure 1).

Type and Size of Letters

Provide the maximum contrast between color field and legend (Table 3). Table 4 shows the size of letters recommended. Use of standard size letters of 1/2 in. or larger is recommended. For identifying materials in pipes of less than 3/4 in. in diameter and for valve and fitting identification, use a permanently legible tag.

Unusual or Extreme Situations

When the piping layout occurs in or creates an area of limited accessibility or is extremely complex, other identification techniques may be required. While a certain amount of imagination may be needed, the designer should always clearly identify the hazard and use the recommended color and legend guidelines.

CHAPTER 35

UNITS AND CONVERSIONS

Table 1 Conversions to SI Units

Multiply	By	To Obtain
acre	0.4047	ha

Note: The Btu, calorie, and kilocalorie are based on the International Table.

CHAPTER 36

PHYSICAL PROPERTIES OF MATERIALS

VALUES in the following tables are in consistent units to assist the engineer looking for approximate values. For data on refrigerants, see Chapter 16; for secondary coolants, see Chapter 18. Chapter 22 gives more information on the values for materials used in building construction and insulation. Many properties vary with temperature, material density, and composition. The references document the source of the values and provide more detail or values for materials not listed here. The preparation of this chapter is assigned to TC 1.3, Heat Transfer and Fluid Flow.

Table 1 Properties of Vapor

	Molecular Mass	Normal Boiling Point, °F	Critical Temp., °F	Critical Pressure, psia	Density, lb/ft^3	Specific Heat, Btu/lb·°F	Thermal Conductivity, Btu/h·ft·°F	Viscosity, lb/ft·h

Volatile Organic Compounds 37.6
THERMAL ENVIRONMENT 37.7
RADIO FREQUENCY RADIATION 37.9
ELECTRICAL HAZARDS 37.10
VIBRATION 37.10
Combustion-Generated Contaminants 37.13

An HVAC practitioner's goal is to provide comfortable and healthy environments for clients. This chapter provides the practitioner with an introduction to the field of environmental health as it pertains to buildings. In many cases, architectural, construction, cleaning, maintenance, and other materials and activities that affect the environment are outside the control of the HVAC designer. But whenever possible, the designer should encourage features and decisions that create a healthy building environment.

EPIDEMIOLOGY AND BIOSTATISTICS

Epidemiology is the study of distributions and determinants of disease. It is the application of quantitative methods to evaluate diseases or conditions of interest. The subjects may be humans, animals, or even buildings. Epidemiology is traditionally subdivided into observational and analytical components. It may be primarily descriptive, or it may attempt to identify causal associations. Some classical criteria for the determination of causal relationships in epidemiology are consistency, temporality, plausibility, specificity, strength of the association, and dose-response relationships.

Observational studies are generally performed by defining some group of interest because of a specific exposure or risk factor. A control group is selected on the basis of similar criteria, but without the factor of interest. Observations conducted at one point in time are considered cross-sectional studies. On the other hand, a group may be defined by some criteria at a specific time, for example, all employees who worked in a certain building for at least one month in 1972. They may then be followed over time, leading to an observational cohort study.

Analytical studies may be either experimental or case-control studies. In experimental studies, individuals are selectively exposed to specific agents or conditions. Such studies are generally performed with the consent of the participants, unless the conditions are part of their usual working conditions and known to be harmless. Sometimes exposures cannot be controlled on an individual basis, and the intervention must be applied to entire groups. Control groups must be observed in parallel. Case-control studies are conducted by identifying individuals with the condition of interest and comparing risk factors between these people and individuals without that condition.

Measurement

All factors of interest must be measured in an unbiased fashion to avoid a subconscious influence of the investigator. The method of measurement should be repeatable and the technique meaningful.

Statistical methods for data analysis follow standard procedures. Tests of hypotheses are performed at a specific probability; they must have adequate power, *i.e.*, if a sample size or a measurement difference between the factors or groups is too small, a statistically significant association may not be found even if one is present.

Results obtained in a specific situation, *i.e.*, in a sample of exposed individuals, may be generalized to others only if they share the same characteristics. For example, it may not be legitimate to assume that all individuals have the same tolerance of thermal conditions irrespective of their heritage. Therefore, the results of studies and groups must be evaluated as they apply to a specific situation. Results obtained from a specific problem may not apply to another problem.

TOXICOLOGY

Toxicology is the study of poisons. Most researchers hold that essentially all substances may function as poisons and that only smaller or larger doses prevent them from becoming harmful. Of fundamental importance is defining which component of the chemical structure predicts the harmful effect. The second issue is defining the dose-response relationships. The definition of dose may refer to delivered dose (exposure that is presented to the lungs) or absorbed dose (the dose that is actually absorbed through the lungs into the body and available for metabolism). Measures of exposure may be quite distinct from measures of effect, because of internal dose modifiers; for example, the delayed metabolism of some poisons because of lack of enzymes to degrade them. In addition, the mathematical characteristics of a dose may vary, depending on whether a peak dose, a geometric or arithmetic mean dose, or an integral under the dose curve is used.

Because humans often can not be exposed in experimental conditions, most toxicological literature is based on animal studies. Recent studies suggest that it is not easy to extrapolate between dose level effects from animals to man. Isolated animal systems, such as homogenized rat livers, purified enzyme systems, or other isolated living tissues, may be used to study the impact of chemicals.

INDUSTRIAL HYGIENE

Industrial hygiene is the science of exposure characterization. It involves measurement, interpretation of the measurements, and setting standards. Measurement methods are specified for various environmental characteristics by several organizations. For example, in the United States the National Institute for Occupational Safety and Health (NIOSH) specifies acceptable measurement techniques (P & CAM methods), as does the American Conference of Governmental Industrial Hygienists (ACGIH). The Occupational Safety and Health Administration (OSHA) may specify which method should be used for some standards.

The preparation of this chapter is assigned to the Environmental Health Committee.

Standards

Standards are set by a variety of agencies. The ACGIH reviews data on a yearly basis and publishes a Documentation of Recommended Threshold Limit Values (TLV), levels that are frequently agreed on as reasonably safe. NIOSH has developed criteria documents for specific standards, generally recommending exposure limits below those of the ACGIH. OSHA sets Permissible Exposure Limits (PEL), which are the only enforceable standards in the United States. However, OSHA limits were developed for 8-h exposures in industrial settings and may exceed levels acceptable to occupants in office, residential, and other spaces for various reasons.

Sampling Strategies

Exposure to something may be measured for various purposes. Ascertaining average exposures in specific areas requires a sampling strategy, *i.e.*, the selection of representative samples. On the other hand, sampling for worst-case exposure requires identifying the potentially highest exposures and measuring those.

In short-term exposures likely to cause health effects and work processes likely to lead to short-term overexposures, sampling periods may have to be short or measurements performed with continuous logging equipment. For example, noise-induced high-frequency hearing loss from explosions may be missed if noise exposures are integrated over 8-h periods. On the other hand, short of thermal burns, peak radiant temperatures may not lead to harmful effects if they are kept relatively short.

Generally, if a random exposure is within 40% of a specific danger level, overexposures are likely. The larger the number of samples and the smaller the standard deviations or the lower the geometric mean of exposures, the less likely overexposures are to occur.

AIR QUALITY

Airborne materials include gases and particulates that may be generated by occupants and their activities in a space. Airborne materials may (1) occur from outgassing and/or shedding of building materials and systems, (2) originate in outside air, and/or (3) be from building operating and maintenance programs and procedures. Airborne particles include bioaerosols, asbestos, man-made mineral fibers, and silica, and gaseous contaminants include radon and soil gases as well as volatile organic compounds.

BIOAEROSOLS

Bioaerosols are airborne microbiological particulate matter derived from viruses, bacteria, fungi, protozoa, mites, pollen, and their cellular or cell mass components. Bioaerosols are everywhere in indoor and outdoor environments.

In the past, much attention was given to saprophytic fungi (nutrients that are derived from dead organic material), probably because of readily available sampling and analytical methods for this type of microorganism. Viruses, rickettsia, chlamydia, protozoa, and many pathogenic fungi and bacteria are more difficult to culture, and air sampling methodology for these agents is less well known (ASTM 1990).

Sources

Microorganisms break down the complex molecules found in dead organic materials and recycle minerals and macromolecules to simple substances such as carbon dioxide, water, and nitrates. These components are then used by green plants. Thus, the presence of saprophytic bacteria and fungi in the soil and in the atmosphere is a normal occurrence. For example, the spores of *Cladosporium*, a fungus commonly found on dead vegetation, are almost always found in outdoor air. *Cladosporium* spores are also found in indoor air, depending on the amount of outdoor air that infiltrates into interior spaces or is brought into the HVAC system. Bacteria that are saprophytic on human skin (*Staphylococcus*) and viruses (Influenza A) that are obligate parasites in the human respiratory tract, are shed from humans and are thus commonly present in indoor environments.

Although microorganisms are normally present in indoor environments, the presence of abundant moisture and nutrients in interior niches amplifies the growth of some microbial agents to the extent that the interior environment is microbiologically atypical. Thus, certain types of humidifiers, water spray systems, and wet porous surfaces can be reservoirs and sites for growth of fungi, bacteria (including actinomycetes), protozoa, or even nematodes (Strindehag *et al.* 1988, Arnow *et al.* 1978, Morey *et al.* 1986, Morey and Jenkins 1989). Excessive air moisture (Brundrett and Onions 1980) and floods (Hodgson *et al.* 1985) may cause the proliferation of microorganisms indoors. Turbulence associated with the start-up of air-handling unit plenums may also elevate concentrations of bacteria and fungi in occupied spaces (Yoshizawa *et al.* 1987).

Health Effects

The presence of microorganisms in indoor environments may cause infective and/or allergic building-related illnesses (Morey and Feeley 1988, Burge 1989). Some microorganisms under certain conditions may produce volatile chemicals (Hyppel 1984) that are malodorous or irritative (Holmberg 1987), thus contributing to the development of what is called the sick building syndrome.

Legionellosis refers to two distinct types of illnesses—Legionnaires' disease and Pontiac fever. Legionnaires' disease is a multisystem disease, including pneumonia, with a fatality rate of about 15%. Hospitalization and appropriate antibiotic therapy are required for effective treatment. *Legionella pneumophila*, a recently discovered bacterium (the genus name *Legionella* is derived from the American Legion Convention in Philadelphia in 1976), is the microorganism closely associated with infectious disease in buildings. Cooling towers, evaporative condensers, and domestic water service systems (particularly hot water) all provide water and nutrients for amplification of microorganisms such as *Legionella*. Growth of microbial populations to excessive concentrations is generally associated with inadequate preventative maintenance of these systems. Pontiac fever is milder and nonpneumonic. Recovery usually occurs without hospitalization or use of antibiotics.

There are 31 species and 50 serogroups of *Legionella* identified to date. These gram-negative bacteria are naturally occurring and associated with nonsaline surface waters. Many of these species have not been associated with human disease; however, the *Legionella pneumophila* serogroup 1 is most frequently isolated from nature and most frequently associated with disease. Because *Legionella* requires special nutrients for growth and does not produce resistant endospores, this microorganism is difficult to recover from the air. Collection and analysis of water samples is usually relied on for the detection of *Legionella*, *e.g.*, from cooling towers. Although some strains of the bacterium have not yet been associated with human disease, probably because of their rarity, all *Legionella* strains should be considered potentially pathogenic.

Outbreaks of infective illness in the indoor air may be caused by other types of microorganisms, such as viruses. For example, most of the passengers in an airline cabin developed influenza following exposure to one acutely ill person (Moser *et al.* 1979). In this case, the plane had been parked on a runway for several hours with the ventilation system turned off.

Histoplasmosis, an infective illness caused by the fungus *Histoplasma capsulatum*, has occurred (very rarely) as a building-related illness among individuals involved in the removal of bat droppings in abandoned buildings (Bartlett *et al.* 1982) and among chicken coop cleaners. Presumably asexual spores (conidia) from this fungus were inhaled by workers who removed droppings without adequate respiratory protection.

Microorganisms may cause building-related illness in indoor environments by affecting the immune system. Thus, allergic respiratory illness may develop due to the inhalation of particulates containing microorganisms or their components, such as spores, enzymes, and cell wall fragments. Numerous cases of allergic respiratory illness (humidifier fever, hypersensitivity pneumonitis) report affected people manifesting acute symptoms such as malaise, fever, chills, shortness of breath, and coughing (Hodgson and Morey 1989, Edwards 1980, Morey 1988). In buildings, these illnesses may occur as a response to microbiological contaminants originating from HVAC system components, such as humidifiers and water spray systems, or other mechanical components that have been damaged by chronic water exposure (Hodgson *et al.* 1985, 1987). Affected individuals usually experience relief only after having left the building for an extended period in contrast to occupants with sick building syndrome, where relief is relatively rapid.

Microbiological contamination is reported to be important in about 5% of the indoor air quality evaluations carried out by NIOSH (Wallingford and Carpenter 1986). This is probably an understatement because neither microorganisms nor the possible importance of microbial volatiles, endotoxins, mycotoxins, nonviable microbial particulates, and viruses may have been investigated. Several recent studies suggest that microorganisms in indoor air quality issues are more important than previously suspected (Burge *et al.* 1987, Brundage *et al.* 1988).

Sampling

The principles of sampling and analysis for microorganisms are reviewed in the ACGIH's, *Air Sampling Instruments Manual* (Chatigny 1983). The ACGIH Bioaerosols Committee has developed assessment guidelines (ACGIH 1989) for the collection of microbial particulates.

Preassessment. Sampling for microorganisms should be undertaken when medical evidence indicates the occurrence of diseases such as humidifier fever, hypersensitivity pneumonitis, allergic asthma, and allergic rhinitis. A walk-through examination of the indoor environment for visual detection of possible microbial reservoirs and amplification sites is recommended before sampling. If a microbial reservoir/amplifier is visually identified, it is useful to obtain a bulk or source sample from the reservoir or amplifier. Also, removal of clearly identified reservoirs and amplifiers are preferable to complicated and costly air sampling procedures.

Air sampling. The same principles that affect the collection of an inert particulate aerosol also govern air sampling for microorganisms (ACGIH 1989). However, it is essential that the viability and/or antigenicity of the microbial particulate be protected. In general, culture plate impactors, including multiple- and single-stage sieve devices as well as slit-to-agar samplers, are most useful in office environments where low concentrations of fungi and bacteria are expected. However, not all microbes will grow on the same media; thus, liquid impingement subculturing may be more suitable. Filter cassette samplers are useful for microorganisms or components of microorganisms (*e.g.*, endotoxin) that are not affected by desiccation.

Data interpretation. Rank order assessment is a method used to interpret air sampling data for saprophytic microorganisms (ACGIH 1989). Individual taxa are listed in descending order of abundance for a complainant indoor site and for one or more control locations. The predominance of one or more taxa in the complainant site, but not in the control sites, suggests the presence of an amplifier (for that taxa). In the example in Table 1, Tritirachium and Aspergillus species (fungi) were the predominant taxa present in complainant locations in an office building, where Cladosporium and Fusarium dominated outdoor collections. In this case, Tritirachium and Aspergillus were being amplified in the building.

Table 1 Example Case of Airborne Fungi in Building and in its Outdoor Air

Location	cfu/m^3	Rank Order Taxa
Outdoors	210	Cladosporium>Fusarium>Epicoccum>Aspergillus
Complaint Office #1	2500	Tritirachium > Aspergillus > Cladosporium
Complaint Office #2	3000	Tritirachium > Aspergillus > Cladosporium

1. cfu/m^3 = Colony-forming units per cubic metre of air.
2. Culture media was malt extract agar (ACGIH 1989).

Guidelines

At present, numerical guidelines for bioaerosol exposure in indoor environments are not available for the following reasons (Morey 1990):

- Incomplete data on concentrations and types of microbial particulate indoors, especially as affected by geographical, seasonal, and type-of-building parameters
- Absence of data relating bioaerosol exposure to building-related illness
- Enormous variability in kinds of microbial particulate including viable cells, dead spores, toxins, antigens, and viruses
- Large variation in human susceptibility to microbial particulate, making estimates of health risk difficult

However, even in the absence of numerical guidelines, bioaerosol sampling data can be interpreted based on several considerations:

- Rank order assessment of the kinds (genera species) of microbial agents present in complainant and control locations (ACGIH 1989)
- Medical or laboratory evidence that a building-related illness is caused by a microorganism (ACGIH 1989)
- Indoor/outdoor concentration ratios for various saprophytic microbial agents (Morey 1989, 1990)

For a microorganism to cause a building-related illness, it must be transported in sufficient dose to the breathing zone of a susceptible occupant. Thus, the concepts of reservoir, amplifier, and disseminator need to be understood and considered in interpreting data.

ASBESTOS

The term asbestos refers to a group of naturally occurring silicates that occur in fiber bundles with unusual tensile strength and fire resistance. They are found in two main forms—serpentine, containing only chrysotile, and amphiboles, containing amosite, crocidolite, tremolite, anthrophyllite, and actinolite. Exposure can occur in four settings—production (mining and milling), materials production (insulation, brake linings, etc.), construction, and removal.

Health Effects

Groups of health effects are widely recognized. All clearly follow a dose-response pattern, *i.e.*, the more intense and the longer the exposure, the greater the likelihood of the disease.

Asbestosis. Asbestosis refers to a chronic disease of the lung tissue, leading to scarring, and in end stages, respiratory failure

because of inadequate ability to transport oxygen across the lung tissue. This disease is associated not only with disability, but it also gives rise to elevated lung cancer rates. Exposure levels have been reduced substantially in the last 30 years, so new cases of this disease are seen only rarely in developed countries.

Lung cancer. Lung cancer is a chronic, progressive, generally incurable disease; less than 13% of individuals with the disease survive after 5 years. Many risk factors are recognized, although over 85% of cases are attributed to cigarette smoking. Occupational exposure to asbestos is associated with elevated rates of lung cancer in occupations and industries where asbestos is found. Some industries and trades with previously uncontrolled exposures had a 10 to 20-fold higher rate of lung cancer than those found in the general population; more recently, some building trades with regular asbestos exposure have only a 50% elevation. Where adequate protection exists, no excess is seen.

Mesothelioma. Asbestos exposure is associated with a rare tumor of the pleura (lining of the lung) and peritoneum known as mesothelioma. It is a sentinel event for asbestos exposure, *i.e.*, if the disease is seen, asbestos exposure is almost certainly to have occurred, and other people in the same group may be at risk. The disease is generally progressive, leading to death within a year.

There is some controversy about the relative ability of various forms of asbestos to cause disease. Some researchers find that chrysotile, uncontaminated with amphiboles, is not associated with mesothelioma.

Other diseases. A variety of other diseases have been associated with asbestos exposure, including cancers of the larynx and gastrointestinal tract (esophagus, stomach, colon, and rectum). This relationship to other diseases has not been clearly established, as each has other risk factors and is not strongly associated with asbestos exposure.

Sampling and Assessment

Exposure assessment follows several guidelines, including an inspection procedure and sample collection. Environmental monitoring involves both visual assessment and, where appropriate, bulk sampling, including core drilling, and air sampling.

Asbestos is identified through phase contrast or transmission electron microscopy after collection on filters, or through polarized light microscopy.

Guidelines

Asbestos use in the United States is strictly regulated through federal agencies. OSHA has jurisdiction in the workplace, with an overall permissible exposure limit set the same for both general industry and construction. The Environmental Protection Agency (EPA) regulates asbestos use and exposure in a variety of other settings, including schools and residential environments. Use guidelines are provided, including a document on safe handling and abatement/remediation.

MAN-MADE MINERAL FIBERS

Man-made mineral fibers (MMMF), also known as man-made vitreous fibers (MMVF), are synthetic, amorphous, noncrystalline vitreous structures. They are used primarily as reinforcement, textiles, and insulation materials. Their specific composition varies, some being made from naturally occurring products, such as rock wool from rocks, others from slags. Table 2 presents an overview of their general structure. Even though their source material defines their chemical composition, they have similar physical characteristics.

Since they are amorphous, they do not split lengthwise, as do crystalline fibers such as asbestos. They break across their diameter, leading to progressively shorter pieces. Under the influence of high temperatures, refractory fibers may change their chemical/physical characteristics to crystalline silica.

Table 2 Types of Man-Made Mineral Fibers

Type	Source Material
Continuous fibers	Glass
Insulation wool	Glass wool
	Rock wool
	Slag wool
Special purpose fibers	Glass microfiber
Refractory fibers	Ceramic
	Others

Health Effects

Three broad categories of possible health effects from man-made mineral fibers are possible, although they are not all likely.

Dermatitis. Fiberglass dermatitis is well recognized. Itching and erythema (reddening of skin) after dermal exposure among installers is common. Two mechanisms have been demonstrated. Most cases are due to simple irritation; rarely are true allergies (usually from the coatings applied to the fibers for binding etc.) seen. The diagnosis is easily made if complaints stop after showering. Allergic contact dermatitis requires patch-testing for diagnosis. No long-term health effects have been described.

Microbial contamination. The potential for microbial contamination of porous materials (duct liners and filters) with molds and spores has been widely discussed. Some conditions (moisture, nutrients, temperature) can amplify microbial populations. Two consequences are recognized. First, exposure to specific microbial agents may sensitize some individuals. While individuals (with atopy) are more likely to become sensitized, many nonatopic individuals suffer similar problems. Second, microbial agents may give off specific products, such as aldehydes or complex elaborated toxins, which have more complex health effects.

The relationship between filtration, water incursion, and microbial growth are not clear. Some researchers consider inadequate filtration a primary cause of contamination.

Lung disease. Several surveys have examined the relationship between MMMF exposure and interstitial lung disease, the kind of disease associated with asbestos exposure. Weill *et al.* (1983) and Hughes *et al.* (1993) found no such effects. Kilburn *et al.* (1992) measured some radiographic abnormalities, but these involved persons also exposed to asbestos and welding fumes, both associated with lung disease. At present, there is no evidence that MMMF causes interstitial lung disease.

Cancer and mesothelioma. Man-made mineral fibers have been suspected of leading to elevated cancer rates (WHO 1988). Several mortality studies, in the United States and Europe, have suggested a mild increase, ranging from 10 to over 50%, among MMMF workers. However, in these studies, other factors (asbestos and smoking) were present and probably account for the apparent increase in death rate. When smoking habits were examined, it was found that MMMF workers in the study smoked more than the general control population. When investigators statistically controlled for the effect of smoking, the excess disappeared. Another factor is the asbestos fibers found in the autopsies of the MMMF workers. This led to the conclusion that the excess death rate might also be due to asbestos fibers, which were usually used in the same plants.

One consideration is that most MMMF are simply too large to reach the lungs, as they are filtered out in the upper airways. However, because the man-made mineral fiber can break into shorter pieces, the smaller fragments may reach the airways and lung tissue. Further, refractory fibers fired at a high temperature may have relatively small aerodynamic diameters, enabling them to reach and lodge in the lungs, and not to decay as rapidly. Still, at present there is no clear evidence that any forms of MMMF are

carcinogenic in humans. However, the International Agency for Research on Cancer and the EPA have classified mineral wool and rock wool as possible human carcinogens. This classification appeared before a case-control study which suggested that lung cancer associated with rock wool and mineral wool was more strongly associated with smoking than with occupational exposure to MMMF.

Exposure

Some data exist on exposure likely to occur in buildings. Background levels are almost uniformly below 0.1 fibers per millilitre (f/mL). Substantial exposures occur primarily in production facilities. Studies on fiberglass batt application measured exposure in the range of 0.4 to 1.0 f/mL. Installation of blown insulation into attics developed exposures of 1.5 to 2.0 f/mL; installing acoustic ceiling tile 0.0028 f/mL; and installing duct insulation 0.05-0.6 f/mL. Further exposure assessment of MMMF installation is under consideration.

Man-made mineral fibers can be measured gravimetrically or counted visually using light or electron microscopy.

Guidelines and Environmental Criteria

OSHA regulates man-made mineral fibers as nuisance dust, at 5 mg/m^3 for general industry and 15 mg/m^3 for construction, specifying gravimetric measurement methods as adequate.

NIOSH proposes a recommended exposure level of 3 f/mL for respirable fibers and a level of 5 mg/m^3 for total fibrous glass.

The ACGIH recommends 10 mg/m^3. Sweden has set a level of 1 f/mL for respirable fibers, and Denmark has set a level of 2 f/mL.

SILICA

Silica consists of silicon dioxide, which is abundant in the earth's crust and is used in the manufacture of glass, refractories, abrasives, buffing and scouring compounds, and lubricants. Its biological effects depend on the grade of the silica. Increasing temperatures in the processing of silica leads to its refinement and increased grade. Higher grades are progressively tridymite, critoblite, and quartz. Diatomaceous earth is considered relatively inert.

Health Effects

Silica is associated with three forms of silicosis—acute, accelerated, and chronic (nodular). They are characterized by an immunologic action of silica in the lungs, leading to progressive tissue destruction and immunological abnormalities. All three are irreversible diseases, although chronic silicosis generally does not progress to cause symptoms. Accelerated and acute silicosis do progress and may be fatal.

Guidelines

Standards have been established separately by OSHA and MSHA. Environmental criteria in fibers per millilitre include:

	OSHA	ACGIH
Amorphous silica	5	10
Diatomaceous earth	5	10
Crystalline		
Cristobalite	0.05	
Quartz	0.05	0.1
Tridymite	0.05	0.05
Tripoli	0.05	0.1

Sampling may occur on particulate filters. Quantification is through low-temperature ashing or X-ray diffraction spectrometry.

RADON AND OTHER SOIL GASES

Radon is a naturally occurring, chemically inert, odorless, tasteless radioactive gas. It is produced from the radioactive decay of radium, which is formed, through several intermediate steps, from the decay of uranium. Since radium and uranium are ubiquitous elements in rock and soil, radon is widely found in the natural environment. Because Radon-222, the decay product of Radium-226, is not chemically bound or attached to other materials, it can move through very small spaces, such as those between particles of soil and rock, and enter indoor environments (Nazaroff *et al.* 1988, Tanner 1980). Additional, but secondary, sources of indoor radon include groundwater and radium-containing building materials.

Radon gas enters buildings through cracks or openings such as sewer pipe and sump pump openings, cracks in concrete, and wall-floor joints. The amount of radon entering and subsequent indoor concentration distribution depends on several factors, including the concentration of radium in the surrounding soil or rock, the soil porosity and permeability, and the air pressure differential between the building and the soil or between various indoor spaces which may result from the stack effect, operation of exhaust fans, or operation (or lack of) HVAC equipment.

Average concentrations of radon in homes in the United States is about 55 Bq/m^3 (1.5 pCi/L), with a log normal concentration distribution. Although approximately 93% of homes have concentrations three times below this average (150 Bq/m^3)(4 pCi/L), homes with higher concentrations are not uncommon, and some have been found with concentrations exceeding 4000 Bq/m^3 (110 Pci/L). While several sources of radon may contribute to average radon levels in homes, pressure-driven flow of soil gas constitutes the principal source. With the exception of a few homes with private water wells, where radon in water can be important, soil gas constitutes the only significant source in homes with elevated concentrations (Nazaroff 1987, Akerblom 1984, DSMA 1983).

Health Effects

The radioactive decay of radon produces a series of radioactive isotopes of polonium, bismuth, and lead. Unlike their chemically inert radon parent, these progeny are chemically active and can adhere to dust particles or other surfaces and can, on inhalation, also attach to the airways of the lung. Two of these progeny are alpha emitters, and the passage of these particles through the tissue lining the lung can cause lung cancer (Samet 1989). Thus, the health effects associated with radon are mainly due to exposures to these radon decay products, and the amount of risk is assumed to be directly related to the total exposure. Studies of uranium and other underground mines form the principal basis for knowledge about health risks due to radon. These studies have also identified synergistic effects between smoking and radon progeny exposure, so that smokers will have a greater risk of lung cancer than non-smokers if both are exposed to the same radon concentration.

Measurements

Indoor concentrations of radon can vary hourly, daily, and seasonally, in some cases by as much as a factor of 10 to 20 on a daily basis (Scott 1989, Turk 1990). For example, measurements made during a mild spring may underestimate the annual average level because of ventilation from open windows or the operation of HVAC equipment (*e.g.*, economizer operation, which increases outdoor air ventilation rates). Similarly, indoor levels during a cold winter may be higher than average because the building is sealed and the outdoor air ventilation rates are minimized. Thus, longer-term measurements (6 months to 1 year) made during normal use generally provide more reliable estimates of the average indoor concentration.

Two techniques widely used for homeowners' measurements are the charcoal canister (short-term) and the alpha track (long-term) methods. Generally, short-term measurements should only be used as a screening technique to see if a long-term measurement is necessary. The great uncertainties in measurement accuracy (which, for concentrations in the range found in most homes, is approximately 50%), as well as the natural variability of radon concentrations should be considered.

Controls

Exposure to indoor radon may be reduced by (1) preventing radon entry, or (2) removing or diluting radon or radon decay products after entry. The first approach is more desirable, especially if it does not require large maintenance or energy expenditures. The most effective measures are generally those that limit soil gas entry into the building (Turk 1991). One of the most common techniques is subslab depressurization, in which the pressure below the floor slab is reduced so that air between the house substructure and the soil tends to flow out of rather than into the building. Other techniques, such as basement pressurization, have been attempted with some success.

Although sealing various parts of the building substructure has been attempted, it is often not completely effective by itself, since some openings in the building shell may not be accessible or new openings can develop with time. Because furnaces or HVAC systems can contribute to the depressurization of buildings, the location and tightness of supply and return ducts are important, especially in new construction.

Soil-Gas Transportation of Other Pollutants

Evidence from some studies suggest that contaminants other than radon may enter buildings from the surrounding soil, although the extent of such occurrences is unknown. For example, methane migrating away from landfills through unsaturated soils has reached explosive levels in nearby buildings. In other instances, potentially toxic and carcinogenic, volatile organic compounds, present in soil gas as contaminants, have been transported into buildings. These compounds may pose health risks in indoor environments, depending on their concentrations and the length of exposure. Some specific examples include the entry of chlorinated solvents into houses near landfills (Wood and Porter 1987, Hodgson *et al.* 1988, Garbesi *et al.* 1989), the entry of gasoline vapors from leaking underground fuel tanks into buildings (Kullman and Hill 1990), and the detection of pesticides in houses in which the underlying soil had been treated (Livingston and Jones 1981, Wright and Leidy 1982).

Any volatile organic compounds present in soil gases in the vicinity of buildings may enter those buildings under certain, as yet undefined, soil and building conditions. Therefore, their presence, or possible presence, should be considered in the design, construction, and operation of buildings—particularly in the vicinity of inactive landfills or hazardous waste sites. Buildings in these areas should be made (1) to minimize substructure leakage, to prevent substructures from being depressurized by the operation of HVAC systems, and (2) to seal duct systems in crawl spaces or beneath slab foundations against the possible intrusion of gases. Techniques installed to prevent entry of radon gas will also prevent entry of other soil gases.

VOLATILE ORGANIC COMPOUNDS

Volatile organic compounds (VOCs) are air pollutants found in all nonindustrial environments. After ventilation, VOCs are probably the first concern when diagnosing an IAQ problem (Morey and Singh 1991). VOCs are organic compounds with vapor pressures greater than about 10^{-3} to 10^{-4} mm Hg (torr). This includes 4 to 16 carbon alkanes, chlorinated hydrocarbons, alcohols, aldehydes, ketones, esters, terpenes, ethers, aromatic hydrocarbons (such as benzene and toluene), and heterocyclics. The entire range of VOCs has been categorized as indicated in Table 3 (WHO 1989). No sharp limits exist between the categories, which were defined by boiling-point ranges.

Table 3 Classification of Indoor Organic Pollutants (WHO 1989)

Description	Abbreviation	Boiling Point Range[a], °F
Very volatile (gaseous) organic compounds[b]	VVOC	< 32 to 120-212
Volatile organic compounds	VOC	120-212 to 460-500
Semivolatile organics (pesticides, polynuclear aromatic compounds, plasticizers)	SVOC	460-500 to 720-750

[a]Polar compounds and higher molecular weight VOCs appear at the higher end of each boiling-point range.
[b]Alcohols, aldehydes, olefins, terpenes, aliphatic aromatic hydrocarbons, chlorinated hydrocarbons.

Even in geographical areas with significant outdoor pollution, indoor total VOC concentrations 2 to 10 times higher have been measured (Wallace 1987). In new office buildings, the total VOC concentration at the time of initial occupancy can be 50 to 100 times that present in outdoor air. The variety of VOCs found in indoor air is almost always greater than that in outdoor air, largely because of the large number of possible sources in indoor environments. Although VOCs in indoor, nonindustrial environments are generally present at concentrations considered to be elevated with respect to the outdoor air, the absolute concentrations of specific VOCs is almost always 100 to 1000 times less than that considered significant in industrial workplaces. However, standards for the industrial workplace are higher than would be appropriate for the general population, which includes the elderly, children, and people who are more sensitive to VOCs than the "average" industrial worker.

Sources

Studies on the sources of VOCs in nonindustrial indoor environments are confounded by the variable nature of emissions from potential sources (Berglund 1988). Emissions from some sources, such as building materials, are continuous and regular, whereas emissions from other sources (*e.g.*, paints used in renovation work) are continuous, but irregular in nature. Emission of VOCs from yet other sources are intermittent and regular (*e.g.*, VOCs in combustion products from gas stoves or cleaning products), or intermittent and irregular (*e.g.*, VOCs from carpet shampoos) (Morey and Singh 1991).

While building and furniture materials are known to emit VOCs (Molhave 1986), ventilation may also transport outdoor pollutants to the indoor environment; so the ventilation system itself may be a source of VOCs (Molhave and Thorsen 1990). Human activity, including maintenance, cleaning, and cooking, is another potential source, as are human metabolism and smoking. Additional sources include liquid process copy machines, printing machines, glue, spray cans, cosmetics, and so forth (Miksch 1982). Yet other sources include chloroform in water; tetrachloroethylene and 1,1,1-trichloroethane from cleaning solvents; and methylene chloride from paint strippers, fresheners, cleaners, and polishers. Formaldehyde, a major VOC, has many sources, but pressed wood products appear to be the most significant.

Normally 50 to 300 volatile organic compounds are found in air samples from most nonindustrial environments using standard sorbent sampling techniques. Each compound seldom exceeds a concentration of about 50 $\mu g/m^3$, 100 to 1000 times lower than

relevant occupational threshold limit values (TLVs) (ACGIH 1988). An upper extreme average total concentration of all volatile organic compounds in normally occupied houses is approximately 20 mg/m^3.

Health Effects

Adverse health effects potentially caused by VOCs in nonindustrial indoor environments fall into three categories: (1) irritant effects, including perception of unpleasant odors and mucous membrane irritation; (2) systemic effects, such as fatigue and difficulty concentrating; and (3) toxic chronic effects, such as carcinogenicity (Girman 1989).

The chronic adverse health effects due to VOC exposure are of concern because some VOCs commonly found in indoor air are human (benzene) or animal (chloroform, trichloroethylene, carbon tetrachloride, p-di-chlorobenzene) carcinogens. Some other VOCs are also genotoxic. Theoretical risk assessment studies indicate that chronic exposure risk due to VOCs in residential indoor air is greater than that associated with exposure to VOCs in the outdoor air or in drinking water (McCann 1987, Tancrede 1987).

A biological model for acute human response to low levels of VOCs indoors is based on three mechanisms—sensory perception of the environment, weak inflammatory reactions, and environmental stress reaction (Molhave 1991). The observations are based on limited investigations, but they do, however, indicate that indoor VOCs may cause discomfort due to odors, irritative symptoms in the eyes, nose, and throat, and headaches at levels well below TLVs. The syndrome may include other related effects, such as decreased productivity and performance, although such effects have not yet been positively identified.

Molhave (1991) tentatively concluded that no irritation should be expected as a result of exposure to TVOC (total VOC) below about 0.2 mg/m^3 for normally encountered indoor air. Outdoor air concentrations are about 0.1 mg/m^3 or below. At concentrations higher than about 3 mg/m^3, complaints occurred in all investigated buildings where occupants experienced symptoms. In controlled exposure experiments, odors are significant at 3 mg/m^3. At 5 mg/m^3, objective effects were seen in addition to the subjective irritation. Exposures for 50 min to 8 mg/m^3 of synthetic mixtures of 20 VOCs lead to significant irritation of mucous membranes in the eyes, nose, and throat.

Sampling

Existing sampling methods for VOCs in industrial workplaces are not readily adaptable to nonindustrial indoor studies. Methods developed for industrial workplaces are often bulky, noisy, and validated for about 0.1 the applicable threshold limit value (TLV). Because concentrations of VOCs found in nonindustrial indoor air are usually 100 or more times lower than industrial TLVs (Lewis 1988), often more sensitive sampling and analytical methods are necessary. Proprietary sorbents and activated charcoal, combined with analysis involving gas chromatography and mass spectrometry, are extensively used for VOC sampling and analysis (Hodgson *et al.* 1989).

Variables such as building age and outdoor air ventilation must be considered when interpreting VOC sampling results. In new office buildings, the indoor/outdoor concentration ratio of total VOCs may be great (Sheldon 1988a, 1988b). With adequate outdoor air ventilation, these ratios often fall to less than 5 to 1 after 4 or 5 months of aging. In older buildings with continuous, regular, and irregular emission sources, indoor/outdoor ratios of total VOCs may vary from nearly 1 when maximum amounts of outdoor air are being used in HVAC systems to greater than 10 during winter and summer months when minimum amounts of outdoor air are being used (Morey and Jenkins 1989, Morey and Singh 1991).

Reducing VOC Exposures

Approaches to reducing indoor exposures to VOCs include the following:

- Use low-emitting products indoors.
- Substitute products where possible to reduce emissions.
- Use products according to manufacturers' directions.
- Increase general ventilation, although this may not be energy-efficient and may not be effective for some sources, such as building materials, where increasing the ventilation six times only decreases the VOC by 50%. For wet process photocopiers (this can be the major source in a building and account for 80 to 90% of TVOC), the effect of ventilation is directly proportional, *i.e.*, doubling the ventilation, halves the VOCs.
- Use volatile organic products when occupant density is lowest.
- Install local ventilation, *i.e.*, local exhaust ventilation, near photocopiers, printers, and other point sources.
- Store organics in well-ventilated spaces.
- Do not store large quantities of products containing volatile organics, especially those used infrequently.

THERMAL ENVIRONMENT

The thermal environment affects human health in that it affects body temperatures, both internally and externally (of the skin). For the normal, healthy adult, internal or core body temperatures are very stable, with variations seldom exceeding 1°F. The internal temperature of a resting adult, measured orally, averages about 98.6°F; measured rectally, it is about 1°F higher (Guyton 1972). The temperature of the core is carefully modulated by an elaborate physiological control system. In contrast, the temperature of the skin is basically unregulated and experiences variations from about 88 to 96°F in normal environments and activities.

Range of Healthy Living Conditions

The environmental conditions for thermal comfort are those that minimize the physiological effort of internal temperature regulation. For a resting person wearing trousers and a long-sleeved shirt, comfort corresponds to a still air environment of about 75°F. A zone of comfort extends about 3°F above and below this optimum level. Physiological efforts to increase heat loss and maintain internal temperatures include increased blood flow (vasodilation) to the skin and sweating. Behavioral efforts that might be initiated by the individual to help in this regard include reducing clothing, reducing activity, and seeking cooler conditions. Physiological and behavioral efforts to reduce and balance heat loss include decreasing blood flow (vasoconstriction) to the periphery, increased metabolism, increased clothing and activity, and/or finding shelter from the cold. Involuntary increases in metabolism are achieved by increasing muscle tone that may eventually result in shivering. Some of the human responses to the thermal environment are summarized in Figure 1.

Cardiovascular and other diseases and the inevitable processes of aging can reduce the capacity or ability of physiological systems to balance heat losses with production. Thus, such persons are less able to deal with thermal challenges and deviations from comfort conditions. Metabolism decreases with aging. This decline in average heat production comes from a declining basal metabolism together with decreased physical activity. The metabolism at 80 years of age is about 20% less than that at 20 years. Therefore, in a given environment, an older person is likely to have a lower core and skin temperature. As a result, persons in their eighties prefer to have the air temperature about 3°F warmer than persons in their twenties. Older people may have reduced capacity to sweat and to increase and decrease skin blood flow and are, therefore, likely to experience greater strain in warm and hot conditions and are less able to prevent the fall of body temperature in cool and cold conditions.

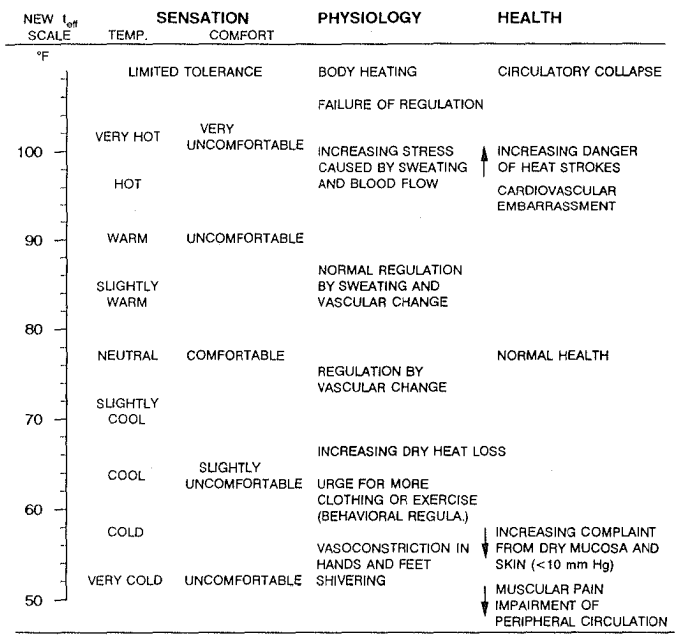

Fig. 1 Related Human Sensory, Physiological, and Health Responses for Prolonged Exposure

Hypothermia

Hypothermia refers to conditions where body temperatures are below the normal range. A temperature decrease reduces the chemical activity of the cells and metabolism. Reduced activity of the nervous system causes sleepiness, irritability, and affects judgement. While mild hypothermia may not cause disease, it impairs the activity and mobility of the immune system, thereby increasing the susceptibility to infections and colds. Thermoregulation is impaired below core temperatures of 94 °F. Consciousness is lost at about 92 °F, and thermoregulation fails completely at 86 °F. Cardiac arrhythmia can develop at temperatures around 82 °F and may lead to fibrillation and death.

In very cold conditions, the skin and peripheral areas of the body can freeze (frostbite). If the tissue is thawed immediately, no permanent damage may result. However, prolonged freezing can permanently damage local circulation and cause tissue loss.

Hyperthermia

Hyperthermia refers to the condition where body temperatures are above normal. A body temperature increase of 4 °F above the normal range does not generally impair function. For example, it is not unusual for runners to have rectal temperatures of 104 °F after a long race.

An elevated body temperature increases metabolism. However, central nervous system function deteriorates at temperatures above 106 to 108 °F and convulsions may occur. At this level, cells may be damaged. This is particularly dangerous for the brain, since lost neurons are not replaced. Thermoregulatory functions of sweating and vasodilation cease at about 110 °F, after which body temperatures may rise very rapidly if external cooling is not imposed.

Seasonal Patterns

Ordinary seasonal changes in temperate climates affect the prevalence of illness. Most acute and several chronic diseases vary in frequency or severity with time of year; some are present only in certain seasons. Minor respiratory infections, such as colds and sore throats, occur mainly in fall and winter; more serious infections, such as pneumonia, have a somewhat shorter season in winter. Intestinal infections, such as dysentery and typhoid fever, are more prevalent in summer. This is also true of encephalitis, endemic typhus, and other diseases transmitted by insects, since insects are active in warm temperatures only.

Many correlations exist between seasonal illnesses and weather (Hope-Simpson 1958, Hemmes *et al.* 1960). These correlations do not establish a causal relationship. Certain aspects of health, such as mortality and heat stress in heat waves, and the effects of hot and cold extremes on specific diseases appear to have a strong physiological basis directly linked to outdoor temperature. Therefore, the effects of outdoor climate should be considered separately from those of indoor climate.

Increased Deaths in Heat Waves

The role of temperature extremes in producing discomfort, incapacity, and death has been studied extensively (Katayama 1970). Physiological studies have focused on military duty or similar work situations (Liethead 1964). The importance of temperature stress, affecting both the sick and well is not sufficiently appreciated. A study of weekly deaths over many years in large U.S. cities by Collins and Lehmann (1953) demonstrates the impact of heat waves in producing conspicuous periods of excess deaths. Heat waves had the same amplitude as lesser influenza epidemics, but were of shorter duration with 7 days as compared to 28 to 42 for influenza.

In an epidemiological study of the effects of an Illinois heat wave in July 1966, daily weather data were related to death rates in various age groups. Concurrent disease (if any), cause of death, sex, age, and race were compared to a similar period in 1965, a normal year for July temperatures. Three hot spells were identified; the first peaked on July 5, the second on July 12, and the last on July 18. Mortality increased 33% during the first spell, 36% during the second, and 10% during the last. Of the population at risk, people over 65 suffered the greatest mortality, attributed largely to lesions in the vascular system of the brain and to other circulatory diseases. This circulatory impairment led to failure of the physiological thermoregulatory system. Females suffered greater losses than males, and whites more than blacks. Studies of heat-related deaths using data collected in the 1939, 1955, and 1963 Los Angeles heat waves showed similar results (Oeschliand Buechley 1970). For an extensive review of heat-related death, refer to Ellis (1972).

Hardy (1971) showed the relationship of health data to comfort on a psychrometric diagram (Figure 2). The diagram contains ASHRAE effective temperature ET* lines and lines of constant skin moisture level or skin wettedness *w*. Skin wettedness is defined as that fraction of the skin covered with water to account for the observed evaporation rate. The ET* lines are loci of constant physiological strain, and also correspond to constant levels of thermal discomfort—slightly uncomfortable, comfortable, and very comfortable (Gonzalez *et al.* 1978). Skin wettedness, an indicator of strain (Berglund *et al.* 1977, Berglund and Cunningham 1986) and the fraction of the skin wet with perspiration, is fairly constant along an ET* line. Numerically ET* is the equivalent temperature at 50% rh that produces the strain and discomfort of the actual condition. The comfort range is between an ET* of 72 and 80 °F, depending on clothing. In this region, skin wettedness is less than 0.2. Heat strokes generally occur when ET* exceeds 93 °F (Bridger and Helfand 1966). Thus, the ET* line of 95 °F is considered dangerous. At this point, skin wettedness is 0.4 or higher. The black dots in Figure 2 correspond to heat stroke deaths of healthy male U.S. soldiers assigned to sedentary duties in midwestern army camp offices (Shickele 1947).

From previous discussion, it is expected that older persons respond less well to thermal challenges than do healthy soldiers. This was apparently the case in the Illinois heat wave study mentioned earlier, where the first wave with a 33% increase in death

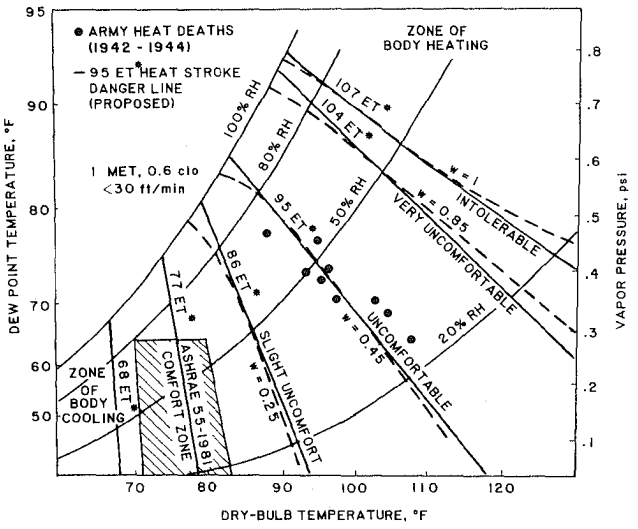

Fig. 2 Isotherms for Comfort, Discomfort, Physiological Strain, Effective Temperature (ET*) and Heat Stroke Danger Threshold

rate and an ET* of 85 °F affected mainly the over 65-year-old group. In the second wave, with an ET* of 93 °F, the observed increase in death rate was 36%. The studies suggest that the "danger line" represents a threshold of significant risk for young healthy people, and that the danger tends to move to lower values of ET* with increasing age.

Effects of Environment on Specific Diseases

Cardiovascular diseases are largely responsible for excess death during heat waves. For example, Burch and DePasquale (1962) found that heart disease cases in which decompensation is present are extremely sensitive to high temperatures and particularly to moist heat. However, both cold and hot temperature extremes are associated with increased coronary heart disease deaths and anginal symptoms (Teng and Heyer 1955).

Both acute and chronic respiratory diseases frequently increase and become more severe during extreme cold weather. No increase in these diseases has been noted with extreme heat. Additional studies of hospital admissions for acute respiratory illness show a negative correlation between acute respiratory illness and temperature after removal of seasonal trend (Holland 1961).

The symptoms of patients with chronic respiratory diseases (bronchitis, emphysema) increase in colder weather. This is thought to be caused by reflex constriction of the bronchi, which adds to the obstruction already present.

Greenburg (1964) revealed evidence of cold sensitivity in asthmatics; emergency room treatments for asthma increased abruptly in local hospitals with severe early autumn cold spells. Later cold waves with even lower temperatures produced no such effects, and years without early extreme cold had no asthma epidemics of this type. The resuspension of allergens caused by resumed indoor heating may account for this phenomenon.

Patients with cystic fibrosis are extremely sensitive to heat because their diminished sweat gland function greatly decreases their ability to cope with increased temperature (Kessler and Anderson 1951).

Itching and chapping of the skin, an annoying affliction that can become severe and disabling, is influenced by: (1) atmospheric factors, particularly cold and dry weather, (2) frequent washing or wetting of skin, and (3) low indoor humidities. Although it is usually a winter (cold climate) illness in the general population, cases of itching and chapping can be caused by excessive summer air conditioning (Susskind 1965, Gaul 1952).

People suffering from chronic illness (heart disease) or serious acute illnesses that require hospitalization are subjected to less temperature stress. Katayama (1970) found that countries with the most carefully regulated indoor climates (Scandinavian countries and the United States) have had only small seasonal fluctuations in recent decades, while countries that use less adequate space heating and cooling exhibit greater seasonal swings in mortality. For example, mandatory air-conditioning in homes for the aged in the southwest has virtually eliminated previously observed mortality increases in heat waves.

Although summer cooling reduces heat stress by removing both sensible and latent heat from the occupied space, winter heating has a mixed effect. It reduces cold stress, but it frequently contributes to greatly reduced relative humidity. Low humidity can contribute to dehydration as well as discomfort and can cause injury to the skin, eyes, nose, throat, and mucous membranes. These dry tissues may be less resistant to infection. Animal experiments also show that infection rates increase with low levels of either ventilation or humidity (Schulman 1962).

In various tests conducted under identical conditions except humidity level, mechanical humidification raised the relative humidity in one space above that in the matched space; no humidified room had a level greater than 50% rh (Green 1979 and 1982, Gelperin 1973, Serati 1969). In each investigation, the humidified rooms showed a reduction in absenteeism and upper respiratory infection—49% reduction in kindergarten children, 6 and 18% in office workers, and 8 and 18% in army recruits. Since occupants in each pair of spaces were subject to the same outdoor conditions and the same indoor air temperature, reductions were attributed to differences in humidity or a related factor (*e.g.*, reduced dust levels and coughing). Therefore, while low humidity does not have a direct pathological effect, it is a contributing factor. A more direct effect of low humidity has been indicated among users of contact lenses on long airline flights in cabins at low humidity. Here, dehydration of the eyes has been blamed for causing irritation and corneal edema or even ulceration of the corneal epithelium (Laviana *et al.* 1988).

Injury from Hot and Cold Surfaces

The skin has cold, warm, and pain sensors to feed back thermal information about surface contacts. When the skin temperature rises above 113 °F or falls below about 59 °F, sensations from the skin's warm and cold receptors are replaced by those from the pain receptors to warn of thermal injury to the tissue (Guyton 1969). The temperature of the skin depends on the temperature of the contact surface, its conductivity, and the contact time. Table 4 gives approximate temperature limits to avoid pain and injury when contacting three classes of conductors for various contact times (CEN).

RADIO FREQUENCY RADIATION

Just as the body absorbs infrared and light energy, which can affect thermal balance, it can also absorb other longer wavelength electromagnetic radiation. For comparison, visible light has

Table 4 Approximate Surface Temperature Limits to Avoid Pain and Injury

	Contact Time				
Material	**1 s**	**10 s**	**1 min**	**10 min**	**8 h**
Metal, water	149 °F	133 °F	124 °F	118 °F	109 °F
Glass, concrete	176 °F	151 °F	129 °F	118 °F	109 °F
Wood	248 °F	190 °F	140 °F	118 °F	109 °F

wavelengths in the range 0.4 to 0.7 μm and infrared from 0.7 to 10 μm, while K and X band radar is 12 and 28.6 mm. The wavelength of electromagnetic waves of a typical microwave oven is 120 mm. Infrared and visible light are absorbed within 1 mm of the surface (ASHRAE 1985). The heat of the absorbed radiation raises the skin temperature and, if sufficient, is detected by the skin's thermoreceptors, warning the person of the possible thermal danger. With increasing wavelength, the radiation penetrates deeper into the body. The energy can thus be deposited well beneath the skin's thermoreceptors making the person less able or slower to detect and be warned of the radiation (Justesen *et al.* 1982). Physiologically, these longer waves only heat the tissue and, because the heat may be deeper and less detectable, the maximum power density of such waves in occupied areas is regulated (ANSI) (Figure 3). The maximum permitted power densities are less than half of sensory threshold values.

ELECTRICAL HAZARDS

Electrical current can cause burns, neural disturbances, and cardiac fibrillation (Billings 1975). The threshold of perception is about (5 mA) for direct current, with a feeling of warmth at the contact site. The threshold is 1 mA for alternating current, which causes a tingling sensation.

The resistance of the current pathway through the body is the resistance of the skin and body core. However, the core is basically a saline volume conductor with very little resistance. Thus, the pathway resistance is essentially the resistance of the skin, which is greatly affected by the skin's hydration and sweating activity. Dry skin has a resistance of about 300 kΩ, but the resistance of wet and/or sweating skin is only about 2000 Ω. Therefore, using Ohm's law, the voltage to produce the current for threshold perception is:

	Current	
Skin	**AC**	**DC**
Dry	300 V	1500 V
Wet or sweating	2 V	10 V

The AC currents necessary to cause pain and involuntary muscle contraction are 3 and 16 mA. The dangerous aspect of alternating electrical current is its ability to cause cardiac arrest by ventricular fibrillation. If a weak alternating current (100 mA for 2 s) passes through the heart (as it would in going from hand to foot), the current can force the heart muscle to fibrillate and lose the rhythmic contractions of the ventricles necessary to pump blood. Unconsciousness and death will soon follow if medical aid can not rapidly restore normal rhythm.

VIBRATION

Vibration in a building originates from both outside and inside the building. Sources outside a building include blasting operations, road traffic, overhead aircraft, underground railways, earth movements, and weather conditions. Sources inside a building include doors closing, foot traffic, moving machinery, elevators, HVAC systems, and other building services. Vibration is an omnipresent, integral part of the built environment. The effects of the vibration on building occupants depend on whether it is perceived by those persons and factors related to the building, the location of the building, the activities of the occupants in the building, and the perceived source and magnitude of the vibration. Factors influencing the acceptability of building vibration are presented in Figure 4.

Whatever the source of vibration, a person will perceive its effect by hearing it, seeing it, or feeling it. It is the combination of these perceptions that will determine human response. Components concerned with hearing and seeing are part of the visual environment of a room and can be assessed as such. The perception of mechanical vibration by feeling it is generally through the cutaneous and kinesthetic senses at high frequencies, and through the vestibular and visceral senses at low frequencies. Because of this and the nature of vibration sources and building responses, it is convenient to consider building vibration in two categories—low-frequency vibrations less than 1 Hz and high-frequency vibrations of 1 to 80 Hz.

Measurement and Assessment

Human response to vibration depends on the vibration of the body. The main vibrational characteristics are vibration level, frequency, axis (and area of the body), and exposure time. A root-mean-square (rms) averaging procedure (over the time of interest)

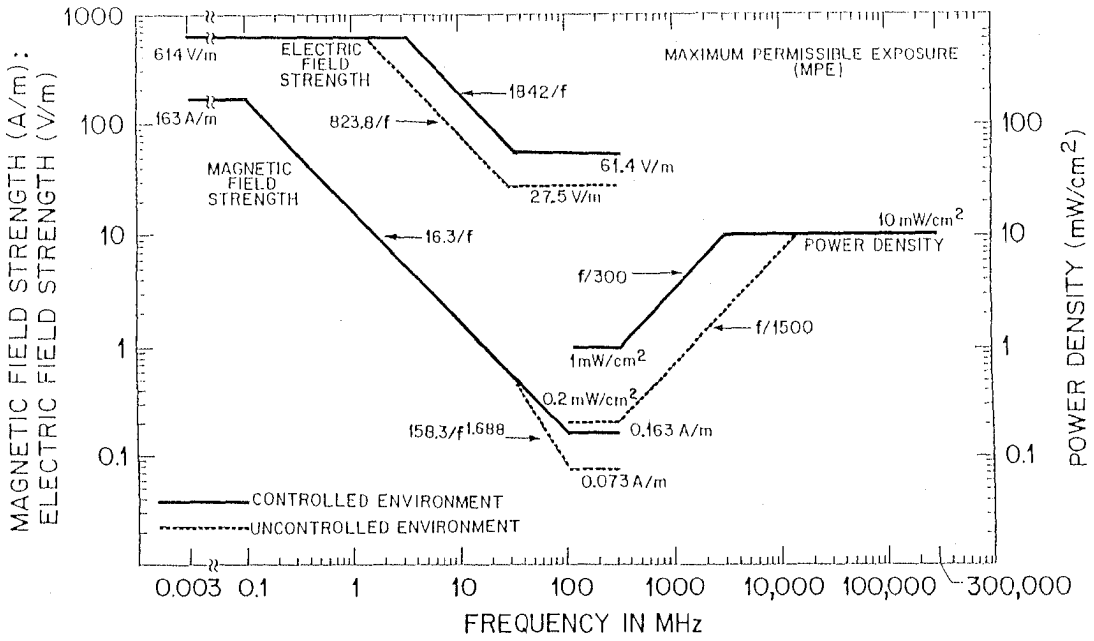

Fig. 3 Maximum Permissible Levels of Radio Frequency Radiation for Human Exposure

is often used to represent vibration acceleration (ft/s^2 rms). Vibration frequency is measured in cycles per second (Hz), and the vibration axis is usually considered in three orthogonal, human-centered translational directions (up-and-down, side-to-side, and fore-and-aft). Although the coordinate system is centered inside the body, in practice, vibration is measured at the human surface and measurements are directly compared with relevant limit values or other data concerning human response.

Rotational motions of a building in roll, pitch, and yaw are usually about an axis of rotation some distance from the building occupants. For most purposes, these motions can be considered as the translational motions of the person. For example, a roll motion in a building about an axis of rotation some distance from a seated person will have a similar effect as side-to-side translational motions of that person, etc.

Most methods assess building vibrations with rms averaging and frequency analysis. However, human response is related to the time-varying characteristics of vibration as well. For example, many stimuli are transient, such as those caused by a train passing a building. The vibration event builds to a peak followed by a decay in level over a total period of about 10 s. The nature of the time varying-event and the number of occasions it occurs during a day are important factors that might be overlooked if data are treated as steady-state and continuous.

Standard Limits

Low-frequency motion (< 1 Hz). The most commonly experienced form of slow vibration in buildings is building sway. This motion can be alarming to occupants if there is fear of building damage or injury. While occupants of two-story wood frame

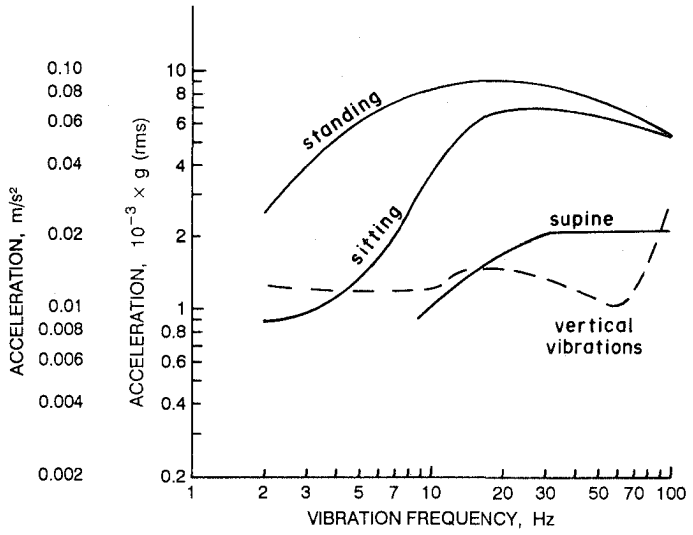

Fig. 6 Median Perception Thresholds to Horizontal (Solid Lines) and Vertical (Dashed Line) Vibrations

houses accept occasional creaks and motion from wind storms or a passing heavy vehicle, such events are not as accepted by occupants of high-rise buildings. Detected motion in tall buildings can cause discomfort and alarm. The perception thresholds of normal sensitive humans to low-frequency horizontal motion are given in Figure 5 (ISO 1984, Chen 1972). The frequency range is from 0.06 to 1 Hz or, conversely, for oscillations with periods of 1 to 17 s. The natural frequency of sway of the Empire State Building in New York City, for example, has a period of 8.3 s (Davenport 1987). The thresholds are expressed in terms of relative acceleration which is the actual acceleration divided by the standard acceleration of gravity ($g = 32.2$ ft/s^2). The perception threshold to sway in terms of building accelerations decreases with increasing frequency and ranges from 5 to 2 milli-g (mg).

For tall buildings, the highest horizontal accelerations generally occur near the top at the building's natural frequency of oscillation. Other parts of the building may have high accelerations at multiples of the natural frequency. Tall buildings always oscillate at their natural frequency, but the deflection is small and the motion undetectable. In general, short buildings have a higher natural frequency of vibration than taller ones. However, strong wind forces energize the oscillation and increase the horizontal deflection, speed, and accelerations of the structure.

Current recommendations state that building motions are not to produce alarm and adverse comment from more than 2% of the building's occupants (ISO 1984). The level of alarm depends on the interval between events. If noticeable building sway occurs for at least 10 min at intervals of 5 years or more, the acceptable acceleration limit is higher than if this sway occurs annually (Figure 5). For annual intervals, the acceptable limit is only slightly above the normal person's threshold of perception. Motion at the 5-year limit level is estimated to cause 12% to complain if it occurred annually. The recommended limits are for purely horizontal motion; rotational oscillations, wind noise, and/or visual cues of the building's motion exaggerate the sensation of motion and, for such factors, the acceleration limit would be lower.

The upper line in Figure 5 is intended for offshore fixed structures such as oil drilling platforms. The line indicates the level of horizontal acceleration above which routine tasks by experienced personnel would be difficult to accomplish on the structure.

High-frequency motion (1 to 80 Hz). Higher frequency vibrations in buildings are caused by machinery, elevators, foot traffic, fans, pumps, and HVAC equipment. Further, the steel structures of modern buildings are good transmitters of high-frequency vibrations. The sensitivity to these higher frequency vibrations is indicated in Figure 6 (Parsons and Griffin 1988). Displayed are the median perception thresholds to vertical and horizontal vibrations in the 2 to 100-Hz frequency range. The average perception threshold for vibrations of this type is from 1 to 9 mg, depending on the frequency and on whether the person is standing, sitting, or lying down.

People detect horizontal vibrations at lower acceleration levels when lying down than when standing. However, a soft bed decouples and isolates a person fairly well from the vibrations of the structure. The threshold to vertical vibrations is nearly constant at approximately 1.2 mg for both sitting and standing positions from 2 to 100 Hz. This agrees with earlier observations by Reiher and Meister (1931).

Many building spaces with critical work areas (surgery, precision laboratory work) are considered unacceptable if vibration is perceived by the occupants. In other situations and activities, perceived vibration may be acceptable. Parsons and Griffin (1988) found that accelerations twice the threshold level would be unacceptable to occupants in their homes.

A method of assessing vibrational acceptability in buildings is to compare the vibration with perception threshold values (Table 5).

Table 5 Acceptable to Threshold Vibration Level Ratios

Place	Time	Continuous or Intermittent Vibration	Impulse or Transient Vibration Several Times per Day
Critical work areas	Day/night	1	1
Residential	Day	2 to 4	30 to 90
	Night	1.4	1.4 to 20
Office	Day/night	4	60 to 128
Workshop	Day/night	8	90 to 128

Note: The ratios for continuous or intermittent vibration and repeated impulse shock are in the range of 0.7 to 1.0 for hospital operating theaters (room) and critical working areas. In other situations, impulse shock can generally be much higher than when the vibration is more continuous.

COMBUSTION-GENERATED CONTAMINANTS

In addition to the water vapor and carbon dioxide produced during combustion processes, air contaminants are generated which include varying amounts of carbon monoxide, nitrogen oxides, sulfur oxides, respirable particles, and polycyclic aromatic compounds.

The term polycyclic aromatic compounds (PAC) is generally used to refer to polycyclic aromatic hydrocarbons (PAH); nitrogen-, sulfur-, and oxygen-heterocyclic analogues of PAH; and other related PAH derivatives. Depending on their molecular weights and vapor pressures, PACs are distributed between vapor and particulate phases. Because PACs are generally produced by combustion, the particulate compounds are found exclusively in the respirable fraction (*i.e.*, $< 2.5\ \mu m$ aerodynamic diameter).

For indoor air in residences and nonindustrial buildings, the principal sources of combustion-generated contaminants include tobacco smoking (cigarettes, pipes, and cigars), wood-burning stoves and fireplaces, unvented space heaters and gas ranges, and flue gas spillage and backdrafting from improperly vented gas- or oil-fired heaters. Infiltration of combustion contaminants generated outdoors into indoor air can also be a significant source of such contaminants indoors.

Environmental tobacco smoke (ETS) consists of exhaled mainstream smoke from the smoker and sidestream smoke which is emitted from the smoldering tobacco. ETS consists of between 70 and 90% sidestream smoke. More than 4000 compounds have been identified in laboratory-based studies, including many known human toxic and carcinogenic compounds such as carbon monoxide, ammonia, formaldehyde, nicotine, tobacco-specific nitrosamines, benzo(a)pyrene, benzene, cadmium, nickel, and aromatic amines. Many of these toxic constituents are more concentrated in sidestream than in mainstream smoke (Glantz and Parmley 1991). In studies conducted in residences and office buildings with tobacco smoking, ETS was a substantial source of many gas and particulate PACs (Offermann *et al.* 1991).

Unvented or improperly vented combustion of natural gas or propane can be a substantial indoor source of nitrogen dioxide and carbon monoxide. When gas flames burn hot and blue, they are fuel lean and produce a minimum of carbon monoxide and a maximum of nitrogen dioxide. When gas flames burn cool and yellow, they are fuel rich and produce a maximum of carbon monoxide and a minimum of nitrogen dioxide. Thus, unvented or improperly vented gas appliances are principally a source of nitrogen dioxide when properly adjusted and principally a source of carbon monoxide when the gas/air ratio is rich, either because of flue failure or improper adjustment. Under fuel-rich conditions, substantial amounts of aldehydes and formaldehyde can also be produced.

Wood-burning fireplaces that are properly vented and have adequate amounts of combustion air normally have sufficient draft to contain most of the combustion contaminants generated within the fireplace from where they are vented up the chimney. Wood-burning stoves can leak combustion contaminants into the indoor air during normal operation and especially during wood loading and/or stoking times. Traynor (1985) reported elevated levels of carbon monoxide, nitric oxide, nitrogen dioxide, and sulfur dioxide in three residences with wood stoves. Offermann *et al.* (1991) identified wood smoke as a likely source of three gas-phase PACs: biphenyl, acenaphthylene, and anthracene.

Laboratory studies of both unvented kerosene and gas space heaters indicate that they can emit significant quantities of carbon monoxide, nitric oxide, nitrogen dioxide, formaldehyde, and respirable particles (Apte and Traynor 1986). Kerosene heaters using sulfur-containing fuel (*e.g.*, grade 2K kerosene) can also generate significant amounts of sulfur dioxide.

Health Effects

The health effects attributed to carbon monoxide exposure range from neuromotor effects, such as decreased attention span and reaction time, to headaches, nausea, and extreme drowsiness, to death by asphyxiation. Carbon monoxide's toxicity is related to the fact that it rapidly and preferentially binds with hemoglobin in blood, thus restricting the hemoglobin's ability to transfer oxygen to body tissues. The United States Occupational Safety and Health Administration (OSHA) recommends a permissible exposure level of 35 ppm. The National Ambient Air Quality Standards (NAAQS), set by the Environmental Protection Agency and designed to protect sensitive individuals, recommend a maximum 8-h average carbon monoxide concentration of 9 ppm for outdoor air. ASHRAE *Standard* 62-1989, Ventilation for Acceptablle Indoor Air Quality, requires that the concentrations of air contaminants in the outside air used for building ventilation not exceed the maximum NAAQS concentrations.

Exposure to nitrogen dioxide (Melial *et al.* 1977) have been related to decreased lung function and increased respiratory disease in children living in homes with gas cooking ranges. While the evidence collected to date is suggestive of such a correlation because of confounding factors related to socioeconomics, the correlation is not definitive. OSHA's recommended permissible 8-h exposure level is 1 ppm, and NAAQS recommends a maximum annual average nitrogen dioxide concentration of 0.05 ppm for outdoor air.

Sulfur dioxide is a well-established respiratory irritant, and levels of sulfur dioxide in homes using unvented kerosene heaters occasionally may be sufficient to induce asthmatic attacks in individuals with hypersensitive airways (Cooper and Alberti 1984). OSHA's recommended permissible 8-h exposure level is 2 ppm, and NAAQS recommends a maximum annual average sulfur dioxide concentration of 0.03 ppm for outdoor air.

Polycyclic aromatic compounds generated by combustion processes include many PAH, nitro-PAH and aza-arenes which have been shown to be carcinogenic in animals (NAS 1983). Other PACs are biologically active as tumor promoters and/or cocarcinogens. High exposures to PAH and aza-arenes have recently been reported for a population in China with very high lung cancer rates (Mumford *et al.* 1987). There are no OSHA or NAAQS exposure guidelines for PACs. The estimated cancer risk for exposure to benzo(a)pyrene, a classical indicator compound for PAH, is 1 per million, for a lifetime exposure to 0.3 ng/m^3 (Offermann *et al.* 1991).

ETS, which is a source of many PACs, has been shown to be causally associated with lung cancer (NRC 1986, U.S. Department of Health and Human Services 1986) and cardiovascular disease (Taylor *et al.* 1992) in adults, and respiratory infections, asthma, middle ear effusion (NRC 1986, U.S. Department of Health and Human Services 1986), and low birth weight in children (Martin and Bracken 1986). The U.S. Environmental Protection Agency is considering classifying ETS as a known human carcinogen (EPA 1992), while the National Institute for Occupational Safety and Health has determined that ETS is potentially carcinogenic to occupationally exposed workers (NIOSH 1991). ETS is also a cause of sensory irritation and annoyance (odors and eye irritation).

Carbon monoxide concentrations may be determined directly with real time instrumentation using either portable infrared spectrometers or electrochemical detectors. Nitrogen oxides and sulfur oxides may be measured using passive or active sorbent collection methods followed by spectrophotometric analysis. PACs may be measured in the sub-ng/m^3 range through collection of large air samples using medium volume samplers (20 to 40 litres per minute for 12 to 24 h). A sampler developed specifically for measuring indoor concentrations of PACs (Loiselle *et al.* 1991)

uses a fluorocarbon resin-impregnated glass fiber filter followed by a cartridge containing XAD-4 sorbent resin. The samples must be extracted in a laboratory and analyzed using gas chromatography and mass spectrometry for the volatile fraction and high-performance liquid chromatography with UV fluorescence for the nonvolatile fraction.

CHAPTER 38

CODES AND STANDARDS

THE Codes and Standards listed in Table 1 represent practices, methods, or standards published by the organizations indicated. They are valuable guides for the practicing engineer in determining test methods, ratings, performance requirements, and limits applying to the equipment used in heating, refrigerating, ventilating, and air conditioning. *Copies can usually be obtained from the organization listed in the Publisher column.* These listings represent the most recent information available at the time of publication.

Table 1 Codes and Standards Published by Various Societies and Associations

Subject	Title	Publisher	Reference
Air Conditioners	Room Air Conditioners	CSA	C22.2 No. 117-1970
Rooms	Room Air Conditioners	AHAM	ANSI/AHAM (RA C-1)
	Method of Testing for Rating Room Air Conditioners and Packaged Terminal Air Conditioners	ASHRAE	ANSI/ASHRAE 16-1983 (RA 88)
	Method of Testing for Rating Room Air Conditioners and Packaged Terminal Air Conditioner Heating Capacity	ASHRAE	ANSI/ASHRAE 58-1986 (RA 90)
	Methods of Testing for Rating Room Fan-Coil Air Conditioners	ASHRAE	ANSI/ASHRAE 79-1984 (RA 91)
	Commercial and Residential Central Air Conditioners	CSA	C22.2 No. 119-M1985
	Performance Standard for Room Air Conditioners	CSA	CAN/CSA-C368.1-M90
	Room Air Conditioners (1982)	UL	ANSI/UL 484-1986
Packaged Terminal	Packaged Terminal Air Conditioners	ARI	ARI 310-90
	Packaged Terminal Heat Pumps	ARI	ARI 380-90
Transport	Air Conditioning of Aircraft Cargo (1978)	SAE	SAE AIR806A
	Nomenclature, Aircraft Air-Conditioning Equipment (1978)	SAE	SAE ARP147C
Unitary	Load Calculation for Commercial Summer and Winter Air Conditioning, 4th ed. (1988)	ACCA	ACCA Manual N
	Application of Sound Rated Outdoor Unitary Equipment	ARI	ARI 275-84
	Commercial and Industrial Unitary Air-Conditioning Equipment	ARI	ANSI/ARI 360-86
	Sound Rating of Outdoor Unitary Equipment	ARI	ARI 270-84
	Unitary Air-Conditioning and Air-Source Heat Pump Equipment	ARI	ANSI/ARI 210/240-89
	Methods of Testing for Rating Heat Operated Unitary Air-Conditioning Equipment for Cooling	ASHRAE	ANSI/ASHRAE 40-1986 (RA 92)
	Methods of Testing for Rating Unitary Air-Conditioning and Heat Pump Equipment	ASHRAE	ANSI/ASHRAE 37-1988
	Methods of Testing for Seasonal Efficiency of Unitary Air Conditioners and Heat Pumps	ASHRAE	ANSI/ASHRAE 116-1983
	Performance Standard for Split-System Air Conditioners and Heat Pumps	CSA	CAN/CSA-C273.3-M91
	Performance Standard for Single Package Central Air Conditioners and Heat Pumps	CSA	CAN/CSA-C656-M92
	Air Conditioners, Central Cooling (1982)	UL	ANSI/UL 465-1984
Air Conditioning	Commercial Low Pressure, Low Velocity Duct System Design	ACCA	Manual Q
	Duct Design for Residential Buildings	ACCA	ACCA Manual D
	Load Calculation for Residential Winter and Summer Air Conditioning, 7th ed. (1986)	ACCA	ACCA Manual J
	Gas-Fired Absorption Summer Air Conditioning Appliances (with 1982 addenda)	AGA	ANSI Z21.40.1-1981
	Heating and Cooling Equipment	UL	ANSI/UL 1995-1992
	Environmental System Technology (1984)	NEBB	NEBB
	Automotive Air-Conditioning Hose (1989)	SAE	ANSI/SAE J51 MAY89
	HVAC Systems—Applications, 1st ed. (1986)	SMACNA	SMACNA
	HVAC Systems—Duct Design (1990)	SMACNA	SMACNA
	Installation Standards for Residential Heating and Air Conditioning Systems (1988)	SMACNA	SMACNA
Transport	Air Conditioning Equipment, General Requirements for Subsonic Airplanes (1961)	SAE	SAE ARP85D
	General Requirements for Helicopter Air Conditioning (1970)	SAE	SAE ARP292B
	Testing of Commercial Airplane Environmental Control Systems (1973)	SAE	SAE ARP217B
Unitary	Method of Rating Computer and Data Processing Room Unitary Air Conditioners	ASHRAE	ANSI/ASHRAE 127-1988
	Method of Rating Unitary Spot Air Conditioners	ASHRAE	ANSI/ASHRAE 128-1988
Air Curtains	Air Curtains for Entranceways in Food Establishments	NSF	NSF-20
	Air Distribution Basics for Residential and Small Commercial Buildings	ACCA	ACCA Manual T
	Residential Equipment Selection	ACCA	ACCA Manual S

Table 1 Codes and Standards Published by Various Societies and Associations (*Continued*)

Subject	Title	Publisher	Reference
Air Curtains (continued)	Flexible Duct Performance and Installation Standards	ADC	ADC
	Laboratory Certification Manual	ADC	ADC 1062:LCM-83
	Test Code for Grilles, Registers and Diffusers	ADC	ADC 1062:GRD-84
	Metric Units and Conversion Factors	AMCA	AMCA 99-0100-76
	Test Methods for Air Curtain Units	AMCA	AMCA 220-91
	Air Volume Terminals	ARI	ANSI/ARI 880-89
	Method of Testing for Rating the Performance of Air Outlets and Inlets	ASHRAE	ANSI/ASHRAE 70-1991
	Standard Methods for Laboratory Air Flow Measurement	ASHRAE	ANSI/ASHRAE 41.2-1987 (RA 92)
	Rating the Performance of Residential Mechanical Ventilating Equipment	CSA	CAN/CSA-C260-M90
	Residential Air Exhaust Equipment (1e)	CSA	C260.2-1976
	High Temperature Pneumatic Duct Systems for Aircraft (1981)	SAE	ANSI/SAE ARP699D
Air Ducts and Fittings	Commercial Low Pressure, Low Velocity Duct Systems	ACCA	Manual Q
	Duct Design for Residential Winter and Summer Air Conditioning	ACCA	Manual D
	Flexible Air Duct Test Code	ADC	ADC FD-72R1-1979
	Pipes, Ducts and Fittings for Residential Type Air Conditioning Systems	CSA	B228.1-1968
	Installation of Air Conditioning and Ventilating Systems (1989)	NFPA	ANSI/NFPA 90A-1989
	Installation of Warm Air Heating and Air-Conditioning Systems (1989)	NFPA	ANSI/NFPA 90B-1989

	Standard Building Code (1991)	SBCCI	SBCCI
Mechanical	Safety Code for Elevators and Escalators (plus two yearly supplements)	ASME	ANSI/ASME A 17.1-1990
	BOCA National Mechanical Code, 7th ed. (1990)	BOCA	BOCA
	Uniform Mechanical Code (1991) (with Uniform Mechanical Code Standards)	ICBO/ IAPMO	ICBO/IAPMO
	Standard Gas Code (1991 ed. with 1992 revisions)	SBCCI	SBCCI
	Standard Mechanical Code (1991 ed. with 1992 revisions)	SBCCI	SBCCI
Burners	Guidelines for Burner Adjustments of Commercial Oil-Fired Boilers	ABMA	ABMA
	Domestic Gas Conversion Burners	AGA	ANSI Z21.17-1984; Z21.17a-1990
	Installation of Domestic Gas Conversion Burners	AGA	ANSI Z21.8-1984; Z21.8a-1990; Z21.176-1990
	General Requirements for Oil Burning Equipment	CSA	CAN/CSA-B140.0-M87 (R 1991)
	Installation Code for Oil Burning Equipment	CSA	CAN/CSA-B139-M91
	Oil Burners; Atomizing Type	CSA	CAN/CSA-B140.2.1-M90
	Pressure Atomizing Oil Burner Nozzles	CSA	B140.2.2-1971 (R 1991)
	Replacement Burners and Replacement Combustion Heads for Residential Oil Burners	CSA	B140.2.3-M1981 (R1991)
	Supplement No. 1 to B139-1976, Installation Code for Oil Burning Equipment	CSA	B139S1-1982
	Vaporizing-Type Oil Burners	CSA	B140.1-1966 (R 1991)
	Commercial-Industrial Gas Heating Equipment (1973)	UL	UL 795
	Oil Burners (1989)	UL	ANSI/UL 296-1988
Capillary Tubes	Capillary Tubes Method of Testing Flow Capacity of Refrigerant	ASHRAE	ANSI/ASHRAE 28-1988
Chillers	Methods of Testing Liquid Chilling Packages	ASHRAE	ASHRAE 30-1978
	Absorption Water-Chilling Packages	ARI	ARI 560-82
	Centrifugal or Rotary Screw Water-Chilling Packages	ARI	ARI 550-90
	Reciprocating Water-Chilling Packages	ARI	ARI 590-86
Chimneys	Design and Construction of Masonry Chimneys and Fireplaces	CSA	CAN/CSA-A405-M87
	Chimneys, Fireplaces, and Vents, and Solid Fuel Burning Appliances	NFPA	ANSI/NFPA 211-1988
	Chimneys, Factory-Built, Medium Heat Appliance (1992)	UL	ANSI/UL 959-1992
	Chimneys, Factory-Built, Residential Type and Building Heating Appliances (1989)	UL	ANSI/UL 103-1988
Cleanrooms	Procedural Standards for Certified Testing of Cleanrooms (1988)	NEBB	NEBB-1988
Coils	Forced-Circulation Air-Cooling and Air-Heating Coils	ARI	ARI 410-91
	Methods of Testing Forced Circulation Air Cooling and Air Heating Coils	ASHRAE	ASHRAE 33-1978
Comfort Conditions	Thermal Environmental Conditions for Human Occupancy	ASHRAE	ANSI/ASHRAE 55-1992
Compressors	Compressors and Exhausters (reaffirmed 1986)	ASME	ANSI/ASME PTC 10-1965 (R 1986)
	Displacement Compressors, Vacuum Pumps and Blowers	ASME	ANSI/ASME PTC9-1974 (R 1992)
	Safety Standard for Air Compressor Systems	ASME	ANSI/ASME B19.1-1990
	Safety Standard for Compressors for Process Industries	ASME	ASME/ANSI B19.3-1991
	Compressed Air and Gas Handbook, 5th ed. (1988)	CAGI	CAGI
Refrigeration	Ammonia Compressor Units	ARI	ANSI/ARI 510-87
	Method for Presentation of Compressor Performance Data	ARI	ARI 540-91

Table 1 Codes and Standards Published by Various Societies and Associations (*Continued*)

Subject	Title	Publisher	Reference
Compressors (continued)	Positive Displacement Refrigerant Compressors and Condensing Units	ARI	ANSI/ARI 520-90
	Method for Presentation of Compressor Performance Data	ARI	ARI 540-91
	Methods of Testing for Rating Positive Displacement Refrigerant Compressors	ASHRAE	ASHRAE 23-1978
	Hermetic Refrigerant Motor-Compressors	CSA	CAN/CSA-C22.2 No. 140.2-M91
	Hermetic Refrigerant Motor-Compressors (1991)	UL	ANSI/UL 984
Computers	Protection of Electronic Computer/Data Processing Equipment	NFPA	ANSI/NFPA 75-1989
Condensers	Commercial Applications Systems and Equipment (for equipment selection only)	ACCA	Manual CS
	Remote Mechanical Draft Air-Cooled Refrigerant Condensers	ARI	ARI 460-87
	Water-Cooled Refrigerant Condensers, Remote Type	ARI	ARI 450-87
	Methods of Testing for Rating Remote Mechanical-Draft Air-Cooled Refrigerant Condensers	ASHRAE	ASHRAE 20-1970
	Methods of Testing Remote Mechanical-Draft Evaporative Refrigerant Condensers	ASHRAE	ANSI/ASHRAE 64-1989
	Methods of Testing for Rating Water-Cooled Refrigerant Condensers	ASHRAE	ANSI/ASHRAE 22-1992
	Addendum 1, Standards for Steam Surface Condensers (1989)	HEI	HEI
	Standards for Steam Surface Condensers, 8th ed. (1984)	HEI	HEI
Condensing Units	Commercial Applications Systems and Equipment	ACCA	Manual CS
	Residential Equipment Selection	ACCA	Manual S
	Commercial and Industrial Unitary Air-Conditioning Condensing Units	ARI	ARI 365-87
	Methods of Testing for Rating Positive Displacement Condensing Units	ASHRAE	ASHRAE 14-80
	Heating and Cooling Equipment	CSA	CAN/CSA C22.2 No. 236-M90
	Refrigeration and Air-Conditioning Condensing and Compressor Units (1987)	UL	ANSI/UL303-1988
Contactors	Definite Purpose Contactors for Limited Duty	ARI	ANSI/ARI 790-86
	Definite Purpose Magnetic Contactors	ARI	ANSI/ARI 780-86
Controls	Quick-Disconnect Devices for Use with Gas Fuel	AGA	ANSI Z21.41-1989; Z21.41a-1990
	Energy Management Control Systems Instrumentation	ASHRAE	ANSI/ASHRAE 114-1986

ADDITIONS AND CORRECTIONS

This section supplements the current handbooks and notes technical errors found in the series. Occasional typographical errors and nonstandard symbol labels will be corrected in future volumes. The authors and editor encourage you to notify them if you find other technical errors. Please send corrections to: Handbook Editor, ASHRAE, 1791 Tullie Circle NE, Atlanta, GA 30329.

1991 HVAC Applications

p. 4.7, Equation (1). The equation should read:

$$w_p = \frac{A(95 + 0.425v)}{Y}[p_w - p_a] \quad (1)$$

p. 7.11, 1st column. Revise the paragraph after item "4. Zoning" in the Design Criteria section to read:

Air-cleaning requirements are taken from Table 1 for operating rooms. A recovery lounge need not be considered a sensitive area. The bacteria concern is the same as for an acute-care facility. The minimum ventilation rates, desired pressure relationships, desired relative humidity, and design temperature ranges are similar to the requirements for hospitals shown in Table 3.

p. 21.9, 1st column, 5th line up. The equation for infiltration heat loss should read:

$$q_i = 0.03\ V N (t_i - t_o)$$

p. 30.25, 1st column. The reference by Diamond and Avery (1986) is a Los Alamos Scientific Laboratory technical applications manual.

p. 36.6, 1st column, 13th line up. Correct reference to read "(Arkin and Shitzer 1979)." Also correct spelling in Bibliography section on p. 36.16.

p. 39.7, 2nd column, 2nd line up. Change "(see Figure 20)" to "(see Figures 18 and 19)."

1992 HVAC Systems and Equipment

p. 2.2, 2nd column, line 3. Change to read: (see section on dehumidification).

p. 2.3, 1st column. In the Humidification section, revise the first sentence of numbered paragraph 2 to read:

2. The use of compressed air to force water through a nozzle into the airstream is essentially a constant wet-bulb (adiabatic) process.

p. 2.3, Figure 5. Change the caption to read:

Fig. 5 Humidification

p. 3.5, Equation (3). Delete subscripts on the numbers.

p. 3.5, Equation (4). The equation only applies at or near sea level.

p. 5.5, left column, lines 7 and 9. Change "mbh values" to read "36×10^3 to 240×10^3 Btu/h and 240×10^3 to 1.5×10^6 Btu/h, respectively."

p. 6.2, 1st column, Equation (2). The equation should read:

$$q_r = \sigma F_e (T_p^4 - T_r^4) \quad (2)$$

Also, the units for σ are in Btu/(h · ft^2 · °F^4).

p. 6.3, 2nd column, 2nd paragraph. The first sentence should read:

Convection in a panel system is a function of the panel surface temperature and the temperature of the airstream immediately adjacent to the panel.

p. 6.3, 2nd column. In Equations (6) and (7):

D_e = equivalent diameter of panel
= 4 × (panel area)/(perimeter)

p. 6.4, 1st column, last paragraph. The first sentence should read:

Figures 7 and 8 may be used to estimate the combined heat transfer from typical ceiling and floor panels.

p. 6.6, Figure 9. Add the following notes to the figure.

Graph based on data from Wilkes and Petersen (1938) for heat removal by natural convection with D_e = 5.5 ft, 2 in. to panel and room air temperature = AUST.

p. 8.1, 2nd column, line 13. Change "barriers" to read "retarders."

p. 9.5, 1st column. At equation for Q add note "at sea level."

p. 9.12, 1st column, near bottom. At equation for Q_r add note "at sea level."

p. 10.6, 1st column. Rewrite item 6 to read:

6. Take off all branch lines from the top of the steam mains, preferably. . .

p. 10.7, 2nd column, line 1. Delete "minimum."

p. 11.16, 2nd column. In the line below Equation (25) the variable should read t_{ta}.

p. 11.5, Figure 4. The arrow showing the direction of flow from the chillers should point up toward the flow meter, not down. Also, the direction of flow shown on the check valves between the central plant circulating pumps and the chillers should be reversed.

p. 12.11, 1st column. Second paragraph should read

Control valves may be sized on the basis of the valve coefficient C_v as follows:

$$Q = C_v\sqrt{\Delta p/s_f}$$

where

Q = flow rate, gpm
C_v = valve coefficient
Δp = pressure drop across valve, psi
s_f = specific gravity of fluid

p. 19.4, 1st column, 5th paragraph. The pressure range should read "0.2 to 2 in. of water," not "50 to 500 Pa."

p. 19.4, 2nd column, 8th line up. Change "3 °C" to read "5 °F."

p. 19.4, 2nd column, last paragraph. Change "19 °C" to read "66 °F." Change "0.06 kW/kW" to read "0.22 kW/ton." Change "23 °C" to read "74 °F." Change "0.23 kW/kW" to read "0.81 kW/ton."

p. 19.5, 1st column. The first word should read "comparison," not "son."

p. 20.1, 1st column, 6th paragraph. Delete reference to "punched cards."

p. 21.11, 2nd column, Equation (28a). Change "h_{ab}" to read "h_{a1}."

p. 35.28, 1st column. The m in the first term of Equation (22) is misplaced. It should be an exponent.

p. 35.29, 2nd column, Equation (30). The equation should read:

$$W_{pi} = \mu_i u_i^2/g \qquad (30)$$

p. 35.29, 2nd column, Equation (34b). Add = sign so it reads:

$$a = \sqrt{-(\partial p/\partial v)_s} = \sqrt{n_s pv} \qquad (34b)$$

p. 35.30, 1st column, Equation (36a). The equation should read:

$$\Omega = g W_p/a_i^2 = \mu(\Sigma u_i^2/a_i^2) \qquad (36a)$$

p. 36.16, 1st column, 3rd paragraph. In the next to the last sentence, change "brake power" to read "brake horsepower."

p. 36.16, 2nd column, 2nd paragraph up. In the sixth line, change "R-12" to read "R-22."

p. 36.18, 1st column. Refer to ANSI/ASHRAE Standard 15-1992, which is the current Safety Code for Mechanical Refrigeration.

p. 37.8, Figure 17. The piping in this figure is improperly routed because it does not keep the condenser water and chilled water circuits positively separated. It will be corrected in the next revision of the chapter.

p. 37.10, Table 1. Revise as follows:

4. Lubricate	Delete Q under V-Belt Drives Add Q under Fan Shaft Bearings
15. Clean	Delete R under Bleed Rate Delete W under Flow Control Valves Add R under Flow Control Valves Add W under Suction Screen
16. Repaint	Delete R under Fill Delete R under Bleed Rate Add R under Casing Add R under Drive Shaft
17. Completely open and close	Delete S under Drive Shaft Add S under Flow Control Valve
18. Make sure vents are open	Delete M under Motor Add M under Gear Reducer

p. 39.3, Table 3. Revise the 2nd part of the table, which lists how to correct flow, head, and power when the impeller diameter varies, as follows:

To correct for flow, multiply by (New diameter/Old diameter)^3.

To correct for head, multiply by (New diameter/Old diameter)^2.

To correct for power, multiply by (New diameter/Old diameter)^5.

p. 42.10, Equation (8). Change constant in the equation to read "4000," not "4."

p. 43.9, Figure 21. Switch upstream and downstream pressure captions. Flow should be from right to left.

p. 43.10, 1st column. The third paragraph should read:

The area of an orifice is changed either by (1) moving a piston or cup across a shear plate, or (2) by increasing pressure (to squeeze the rubber) in a rubber or a grommet type valve.

COMPOSITE INDEX

ASHRAE HANDBOOK SERIES

This index covers the current Handbook volumes published by ASHRAE. Listings from each volume are identified as follows:

F = 1993 Fundamentals
S = 1992 Systems and Equipment
A = 1991 HVAC Applications
R = 1990 Refrigeration
E = 1988 Equipment

The index is alphabetized in a *word-by-word* format; for example, *air diffusers* is listed before *aircraft* and *heat flow* is listed before *heaters.*

Note that the code for a volume includes the chapter number followed by a decimal point and the page number(s) within the chapter. For example, F32.4 means the information may be found in the Fundamentals volume, chapter 32, page 4.
